ARTIFICIAL PNEUMOTHORAX.*

BY MAURICE FISHBERG, M.D.,

NEW YORK,

ATTENDING PHYSICIAN TO THE TUBERCULOSIS PAVILION OF THE MONTEFIORE HOME AND HOSPITAL FOR CHRONIC DISEASES.

IT is a noteworthy fact that practically all the methods of treatment and remedies which have been recommended during the past three or four decades for the relief and cure of phthisis have been stated to exercise their alleged curative effects only during the incipient stage of the disease, when diagnosis is doubtful in a large proportion of cases, and spontaneous cure is not unknown. This has been the case with arsenic and creosote and their derivatives and compounds and of all other medicinal agents lauded at one time or another as cures for pulmonary tuberculosis. Even specific treatment, the various tuberculins, sera, and vaccines, are said to be efficacious only, or mainly, in the incipient stages of the disease and worthless or harmful in progressive and febrile cases and especially in those liable to hemoptysis.

It is, therefore, refreshing to find that the newest method of treatment of pulmonary tuberculosis is recommended for far advanced cases, especially those manifesting a tendency to pursue a rapidly fatal course and showing signs of extensive excavations. When every other method of treatment for checking the progress of the process in the lung has been tried and found wanting, when fever consumes the body, or life is threatened with copious and uncontrollable pulmonary hemorrhages, this method of treatment may be applied with striking success.

This new method of treatment is the induction of an artificial pneumothorax by the introduction into the pleural cavity of sterile and harmless material which will collapse the lung on the affected or more affected side of the chest. The collapsed lung is thus compressed toward its root, exactly like in pulmonary collapse in the most dreaded of complications of phthisis—spontaneous pneumothorax. But while in the latter soon after its occurrence the patient is usually prostrated by pain, shock, orthopnea, cyanosis, etc., which prove fatal in the vast majority of cases, in the artificially induced pneumothorax for therapeutic purposes all these menacing symptoms are absent; indeed, the patient feels quite well and is even able to do ordinary work, notwithstanding the fact that one of his lungs is entirely out of commission.

These differences in the symptomatology of the two varieties of pneumothorax are obviously due to the different modes of origin. In the spontaneous variety we deal with a visceral rent in the pleura and lung, occurring suddenly and immediately collapsing the entire lung and usually establishing a communication between the pleural cavity and a bronchus or tuberculous excavation. Hence the phenomena of shock, dyspnea, etc., and subsequent development of hydrothorax and pyothorax if the patient survives for some time. On the other hand, in artificial pneumothorax only the parietal pleura is punctured by a thin needle, the gas is allowed to flow in slowly by aspiration into the vacuum of the pleural cavity, at intervals and in small quantities at a time, thus avoiding a sudden change in the relations of the thoracic viscera, permitting them to adapt themselves to the new conditions and obviating the phenomena of collapse and the subsequent infection of any exudate that may take place, because there is no communication between the air-filled pleural cavity and the bronchi and lung.

The principle of this method of treatment is not new. Functional rest is one of the best curative agents in many diseases and also in tuberculosis. It has been observed especially in tuberculosis of bones and joints that functional rest is more efficacious than any other known therapeutic agent. Rest has also been used in many other diseases with great success, notably general rest in functional nervous affections as has been worked out by Weir Mitchel; tracheotomy in certain laryngeal obstructions, gastroenterostomy in cancer and especially in ulcer of the stomach, enterostomy in certain diseases of the lower bowels and rectum, etc.

The lung is one of the organs of the body which never rests but expands and contracts at least 16 times per minute throughout life. With an artificial pneumothorax we can place one lung at rest almost as effectively as the splint puts at rest a tuberculous joint, without endangering the life of the patient. Moreover, the lung is the only organ in the body that is constantly in a state of distention. Even after the most forced expiration it does not collapse completely. Any solution in continuity in the pulmonary tissues remains separated and shows no tendency to bring about the union of the diseased parts or to facilitate the process of healing by coaptation. Inflating gas into the pleural cavity and collapsing the lung we achieve two objects: The lung is immobilized at its root, as was already mentioned; and it is compressed by the gas in the pleural cavity and the retraction of its elastic tissues. Its volume is greatly reduced, diseased parts and walls of cavities are brought into apposition so that they may cicatrize by the formation of connective tissue.

Pneumothorax does even more than afford rest to the diseased lung. By compression it empties the lung of its contents. The pus and cheesy de-

*Read Before the Eastern Medical Society November 13, 1914.

tritus in cavities, the inflammatory exudates in the alveoli and bronchioles are all squeezed out as from a sponge, removing the main source of toxic absorption. It also limits the diseased focus and prevents its spread, so that the healthy parts of

Fig. 1.—Complete collapse of the right lung by an artificial pneumothorax for a cavity in the right upper lobe.

the lung remain so while the lesion is in time converted into a cicatrix, or is encapsulated. As a result of drainage mixed infection is eliminated and prevented. The fact that the air current entering through the trachea cannot circulate within the collapsed lung tissues prevents superinfection of healthy parts of the organ with emboli of detritus carried from one part to another along the bronchial tree and mixed infection with microorganisms other than tubercle bacilli which may be brought in with the air current is avoided. The circulation of the blood is impeded in the collapsed lung, but there occurs a venous or passive hyperemia which is known as an important factor in the defence of tissues against tubercle bacilli. The comparative protection against tuberculosis enjoyed by cardiacs is ascribed to the venous hyperemia of the lungs. The lymph-channels of the collapsed lung are compressed, as has been shown by Shingu,[1] who subjected animals with induced pneumothorax to the inhalation of soot, and at the autopsy found that the collapsed lung remained free from soot. Animals were compelled to inhale large quantities of soot, and subsequently pneumothorax was induced, and when they were finally killed it was found that the free lung was darker than the collapsed lung. This tends to show that the circulation of lymph, which is the main factor in removing inhaled particles from the lung, is impeded or arrested because of stasis of lymph in the compressed lung. In this manner the absorption of toxins from the lesions into the general circulation is impeded or arrested in pneumothorax, and the clinical phenomena of phthisis, such as fever, nightsweats, weakness, etc., are prevented and the body is thus given an opportunity to recuperate. Moreover, the lymph stream being unable to carry away bacilli from the lesion, the process is localized to the affected areas. These points have been found clinically and at the autopsy table; and experimentally by Forlanini,[2] Brauer,[3] Saugman,[4] Graetz,[5] Warnecke,[6] Drasche,[7] Kistler,[8] Robinson and Floyd,[9] Hamman and Sloan,[10] Kessel and Taschman,[11] and many others.

Forlanini's conception of the therapeutic action of pneumothorax is to the effect that it does not remove the cause of phthisis, nor that it affects the anatomical changes produced by the bacilli in the lung. Pneumothorax simply checks the destructive process. Strictly speaking, it does not cure phthisis as such, but hinders the extension of the destructive process, and favors the cicatrization of the destroyed areas. According to Forlanini, we must accept that if the lung normally was an immobile organ it could not become tuberculous.

Indications.—During the first few years after its introduction artificial pneumothorax was urged only for far advanced cases of phthisis for which everything else had been tried but failed to improve their chances to recover. As a *conditio sine qua non* it was insisted upon that the lesion must be strictly unilateral, and that any involvement of the other side of the chest is a contraindication to the treatment. Murphy[12] and Lemke,[13] however, have from the very beginning advised that all cases of phthisis, even those in the incipient stages of the disease, should be treated with this method, provided there are no extensive adhesions preventing the introduction of gas into the pleural cavity. In fact, Lemke says distinctly that "the earlier the treatment is begun in pulmonary tuberculosis, the better the prognosis." With the increased experience with the method of treatment these two extreme views as to the indications have been modified, and although we have not as yet reached a stage when we can conscientiously advise every patient showing signs of incipient phthisis to submit to pneumothorax treatment, yet we now do not any more exact that the opposite lung must absolutely show no signs of involvement.

The factors entering into the selection of suitable cases are the following:

The Form and Stage of the Disease.—There are numerous cases of phthisis which are doing well, or even recover with or without any treatment, medicinal, specific, climatic, or institutional, and it is, of course, not advisable to subject them to the operation with its potential complications. This is true of mild incipient cases and abortive tuberculosis which occurs more often than is generally appreciated. Fibroid phthisis runs an exceedingly chronic course and the pleura is often extensively involved, precluding the introduction of gas into the hemithorax most affected cannot be treated by

Fig. 2.—Complete collapse of the left lung by an artificial pneumothorax for a cavity and repeated and copious hemorrhages. Although the right lung is evidently affected, all the functional symptoms have disappeared and the patient has not bled for eight months.

this method. This is also true of the most common forms of fibroid phthisis characterized by diffuse fibrosis all over both lungs, and it would be sheer folly to treat but one side of the chest. On the other hand, in the later stages of diffuse fibrosis

when excavations form in one lung, the question of pneumothorax is to be considered, provided, of course, that the pleura is free from dense and extensive adhesions.

It is the acute and progressive form of phthisis in which artificial pneumothorax finds its best indications and shows the best and most striking therapeutic results. In the group of cases known as galloping consumption, in which the patient is carried off within three to six months by a rapidly progressing infiltration, caseation and excavations, there are many that can be saved by the induction of a pneumothorax. Patients presenting symptoms and signs of caseous pneumonia, acute pneumonic phthisis, provided the affection is unilateral, are benefited by artificial pneumothorax more than by any method of treatment that has heretofore been devised. The disease runs an acute and fatal course with high fever, nightsweats, emaciation, rapid formation of excavations in the lung, and within three to six months the patient succumbs. It is fortunate that dense pleural adhesions are exceptional in these cases and a pneumothorax can be easily created. The results are often astonishing—with the collapse of the lung the tachycardia, fever, nightsweats, cough, expectoration, etc., disappear, and within a few weeks the patient is reinvigorated and may continue to gain in weight and strength indefinitely.

Another group of cases in which artificial pneumothorax renders excellent service are those which have recurrent, copious and uncontrollable hemorrhages. While when afebrile the patients are not in grave danger, and death due to exsanguination is exceedingly rare, yet our efforts to prevent recurrence of hemorrhage after one has been stopped by keeping the patient in bed for several weeks are often futile, and he, as well as those around him, are discouraged. I have had some patients who had to remain in bed for two or three months with slight but protracted hemorrhages one following another. With the induction of a pneumothorax, provided we succeed in completely collapsing the lung, we have an excellent means of controlling the hemorrhage, prevent its recurrence, and in addition to give the tuberculous focus an opportunity to heal.

At the Montefiore Home we induced pneumothorax in three cases of copious hemorrhage with striking success. In one the patient has had several attacks of hemoptysis. The last one becoming uncontrollable was promptly stopped by a pneumothorax and has not recurred in six months. In the second the profuse hemorrhage was stopped, but the patient succumbed four weeks later from tuberculous bronchopneumonia. A third case of hemorrhagic phthisis has not bled for eight months since a pneumothorax was induced.

It is obvious that only one lung may be compressed while the second must be left to carry on the functions of respiration, and that it is useless to combat a lesion in one lung while the disease is smouldering or progressing in the other. For these reasons it has been found advisable to apply pneumothorax only in unilateral cases. But as a matter of fact, in more or less advanced phthisis, unilateral lesions are hardly if ever met with. Klemperer[14] says that he hardly knows of a case in which one lung was extensively involved and the other remained free from the disease in the anatomical or bacteriological sense. Clinical experience is supported in this regard by autopsy findings. Knopf's[1] experience at the Riverside Hospital in New York City, where among 300 to 400 cases treated annually hardly one is seen with a tuberculous lesion confined to one side, is confirmed by every one who meets many consumptives. Inasmuch as strictly incipient cases are not to be treated by this method for reasons already stated, it is evident that in nearly all cases in which pneumothorax is indicated there will be found signs of involvement of both lungs and we must be satisfied with mild or moderate lesions on the untreated side.

In estimating the chances of success in bilateral cases we need not trouble about the loss in the respiratory area of the lung. The fact that one complete lung is brought out of commission does not mean that if the respiratory area of the other is somewhat curtailed by disease, it will not be able to adequately carry on the function of respiration. Experimental physiology and clinical experience show clearly that nature has been prodigal in this respect, just as is the case with all organs which are double. They have a much larger area of functionally active tissue than the organism requires. Thus the kidneys have been found to be four times as large as is absolutely necessary to sustain life; the adrenals even eleven times. As regards the lung Bernard, Le Play and Mantoux[16] have found that life is compatible with only one-sixth of the total lung capacity; Riva Rocci and Cavallero[17] experimenting on dogs found that pneumothorax does not cause severe dyspnea during rest, nor materially interfere with the chemical processes of respiration, as long as one-third of the respiratory area retains its function. Of course, movement of the animal soon produces dyspnea. Under the circumstances cases of phthisis in which the extent of destruction of lung tissue will be the problem are rare indeed. What should concern us most in the selection of cases is the activity of the process in the untreated lung.

In practice we find that in the vast majority of moderately and far advanced cases the lesions are extensive and active in one lung, while in the opposite there is limited involvement, or signs of quiescent or healed lesions. Though not strictly unilateral, these cases can be successfully treated by pneumothorax if not prevented by pleural adhesions.

It is interesting that careful clinical and pathological observation has shown that only exceptionally is the untreated lung unfavorably influenced. In spite of the increased functional activity because of the vicarious work it is compelled to do, the lung usually remains in the same condition as it was before the opposite lung was collapsed. The vicarious emphysema which is, as a rule, produced increases its size and dilates the alveoli and bronchioles, thus permitting as much air to be passed through as before, when both lungs were active. Forlanini,[2] Saugman,[4] Robinson,[9] Floyd,[19] Hamman,[20] von Adelung,[18] Lyon,[20] and others have reported cases in which active lesions in the untreated lung have improved or healed after a pneumothorax was induced in the more affected side. The factors operative in such cases are not well understood. Carpi[21] has pointed out that amphoric sounds and râles are often altogether transmitted from the more affected side and that diagnosis is very difficult. This may explain in some cases the disappearance of râles in the untreated side. On the other hand the increased blood supply may have

something to do with it. The diminution in toxic absorption from the ulcerating and excavated lung may give the patient a chance to recoup his natural reparative forces unhampered by the toxemia from extensive suppurating areas. However, this is not

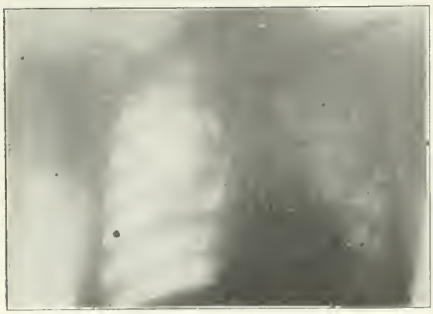

Fig. 3.—Partial pneumothorax of right lung for cavity in the upper lobe. Adhesions prevented complete collapse. Marked amelioration in the symptoms, but cough and expectoration have not ceased altogether, and a complicating pleural effusion has contributed to make this case not a complete success.

the rule. In some lesions in the untreated lung flare up and extend, as has happened in two of my cases. In two of my cases copious hemoptysis even occurred from the untreated lung.

Recently Forlanini and many others have argued that all advanced cases should be given an opportunity to benefit by artificial pneumothorax. In far advanced bilateral or "hopeless" cases one side is as a rule extensively involved, while the other side shows only limited involvement, though the lesion may be evidently active. In such cases it is urged that the more affected side should be treated on the principle that there is nothing to lose and everything to gain. Forlanini's experience has taught him that when the untreated side has but a limited, even though active focus, the chances of success are better than would be expected *a priori*. When both sides are extensively affected the chances of recovery are slim indeed, but improvement in the general condition may be anticipated and a prolongation of life is not unlikely. At times, Forlanini says, we may be astonished that even such patients are cured. In most cases the removal or diminution of toxic absorption gives the patient an opportunity to muster his natural forces of resistance and comfort often superior to that obtained in operative procedures for incurable cancer of the stomach.

There is another important point to be borne in mind: We are not always able to ascertain positively whether the lesion in the less affected side is active, quiescent, or even healed. Râles and amphoric breath sounds heard over a given area of the chest wall are not always autochtonous, but in fact transmitted by conduction from the opposite side, and this is at times very difficult to differentiate, as has already been mentioned. Indeed, perfect symmetry of location of râles, especially on both sides of the spine in the upper part of the chest posteriorly should always excite suspicion that it may be transmitted, and on the side on which it is weaker it is probably so. During and after pulmonary hemorrhages also there are often heard râles all over the chest which disappear in the unaffected side within several days, but when audible they give the impression that both lungs are extensively involved. Radiography is of little, if any, assistance in clearing up many of these cases.

Some French and Italian authors have suggested "diagnostic pneumothorax" in cases in which we are uncertain whether the disease is active on both sides. The more affected pleura is inflated with gas and the opposite lung is watched. In cases in which the physical signs of disease are of the transmitted kind, they disappear soon after the lung is collapsed. But in case they persist in spite of a complete pneumothorax and the general condition of the patient is aggravated, the pneumothorax is allowed to be absorbed or, in more urgent cases, the gas is aspirated and the lung permitted to re-expand. I have not resorted to this treatment as yet, because the first cases had to be carefully chosen. Only such as have a favorable prognosis have been selected with a view of popularizing the method against which there has been quite some prejudice. Now that this has been removed to a great extent, because my patients have seen good results in some cases, and they often ask for the treatment, I shall surely treat bilateral cases.

There are some who believe that even incipient cases ought to be treated with pneumothorax. Among these may be mentioned Murphy,[22] Lemke,[15] Forlanini,[7] von Adelung,[18] Piery,[22] and some others. With this I am not in agreement. If the treatment lasted only a certain and limited time, the patient could be informed of the details and given the choice. But inasmuch as we are not in a position to give the patient definite information as to the probable duration of the treatment, and a large proportion of these cases recover under the old and tried methods of treatment, we should not subject mild incipient cases to the dangers, complications and duration of pneumothorax. I still hold that only progressive or hopeless cases are to be given this treatment.

Contraindications.—To some extent the contraindications have already been given while speaking of the indications, but there remain yet to be discussed certain conditions which preclude the induction of an artificial pneumothorax, mainly those de-

Fig. 4.—Complete pneumothorax in a pregnant woman for diffuse infiltration and excavation of the left lung. Although the right lung is evidently affected, all the functional symptoms disappeared, and even a miscarriage has not affected the favorable course of the disease.

pending on the clinical form of the disease, the coexistence of extrathoracic tuberculosis, and of other diseases. Because pneumothorax only acts locally on the treated lung, acute miliary tuberculosis, in which both lungs are usually equally involved, is not suitable for this treatment. Fibroid

phthisis with extensive pulmonary emphysema is not suitable for this mode of treatment, excepting when in addition to the emphysema there is a localized suppurating excavation which is the cause of fever, sweats, cough, expectoration, etc., undermining the patient. An artificial pneumothorax may be applied as a palliative measure.

The most important forms of extrathoracic tuberculosis which complicate phthisis are laryngeal and intestinal involvement. Clinical experience has shown that pneumothorax often relieves these complications to an amazing extent. It appears that when the tuberculous toxemia due to an extensive focus in the lung is removed by a pneumothorax the laryngeal and intestinal lesions often improve and there are even some cases in which complete cure was attained of both, the lung condition and the extrathoracic lesions. A. da Gradi,[23] P. Courmont,[24] Zink,[25] von Adelung,[35] and others have reported such cases, and Forlanini speaks of it, though he confesses his inability to explain it. Conceding that the chances of cure are remote, laryngeal and intestinal complications should not deter us from applying pneumothorax if the case is otherwise suitable, on the principle that there is nothing to lose and everything to gain.

Diseases of the heart, blood vessels, and kidneys have been found to materially lessen the chances of recovery with an artificial pneumothorax, and are therefore mentioned as contraindications to the treatment. They are all accompanied by disturbances of the circulation and the patients do not bear the deprivation of the breathing area of a complete lung. Forlanini, however, has found that when compensation is good, pneumothorax may be induced with chances of success. There are, however, not yet sufficient clinical data to form definite opinions.

Diabetes has not been found to interfere with the successful outcome of an artificial pneumothorax, and the same is true of pregnancy. There have been reported several cases in which pneumothorax was induced in pregnant women who went on to term, were delivered of healthy infants, and continued under the treatment. In one of my cases the woman was six months pregnant when a pneumothorax was induced. The effect on the lung was excellent, complete collapse was attained (Fig. 4) and the general symptoms completely disappeared. The temperature chart (Chart I) shows clearly the effect on the fever which has been so far permanent for six months. But she miscarried four weeks after the first inflation of gas. It is noteworthy that the temperature and the general condition of the patient were not influenced by the miscarriage.

Pleural Adhesions.—These are, strictly speaking, not necessarily contraindications to the induction of a pneumothorax, but they are hindrances to its successful accomplishment. In many cases no nitrogen can be introduced at all because of extensive and dense adhesions and, after several punctures are made, the case is given up as unsuitable for the treatment. Frequently an area is found which is free and some gas is introduced, but furthere attempts to introduce a sufficient quantity to completely collapse the lung meets with failure. This failure may be of various degrees. In some the pleura is free only over a small area and a small pocket of gas can be made, while the rest of the pleura is adherent. No improvement in the condition can be expected, and the treatment must be abandoned. Fig. 6 shows a radiogram of a chest in which we succeeded in introducing gas and creating two pockets above and below in the left hemithorax. But after nine inflations, introducing from 40 to 150 c.c. of nitrogen, we found that even with high pressure the two pockets could not be brought together, and the lung could not be collapsed because it was held tightly by fibrous bands running to the pleura. There was left nothing but to abandon the treatment.

Pleural adhesions often interfere with the treatment in a peculiar way. The pleura is free all over the chest excepting its upper third, over the tuberculous lesion, where it is densely adherent. There may be a cavity in that location surrounded by stiff walls. The result is that while we succeed in collapsing the lower two-thirds of the lung, the part which is diseased and which we aim mainly in collapsing in order to expel the pus and detritus from the purulent cavity and thus prevent toxic absorption and bring about coaptation of its walls with a view of giving them an opportunity to cicatrize, cannot be collapsed and the disease keeps on its usual course. This is notably the case with old cavities having stiff fibrous walls which refuse to yield to the gas pressure. In acute cases such

Fig. 5.—Partial pneumothorax in a case with a cavity and dense pleural adhesions in the right lung. Despite the incomplete collapse and the implication of the left lung, the patient has been doing well.

cavities are not at all encountered. Many failures are due to this condition. Fig. 6 shows a radiogram of such a case. In spite of all efforts to collapse the lung completely, the adhesions around the lesion prevented the collapse of the diseased part of the lung.

At times the pleural adhesions are not very dense, in fact slight adhesions are said to be present in practically all advanced cases of phthisis, and an increase in the pressure while introducing the gas breaks them up and success is finally attained—the lung is completely collapsed.

The proportion of cases suitable for the treatment is very small indeed. Among 210 patients admitted to the Montefiore Home during the year preceding the time of writing this paper we found only 22 which we considered suitable for pneumothorax treatment. This is a rather high percentage and is partly due to the fact that strong efforts were made by me to find suitable patients outside of the institution and induce them to enter. Statistics of most writers seem to indicate that less than 5 per cent. of all cases that come under their observation are suitable for the treatment. Lemke appears to be the only author whose

clinical experience has been to the effect that he had to abandon the operation in but a small proportion of the selected cases, because of pleural adhesions. Perhaps the reason is that he operated on incipient cases. Bernard[24] found among 628 patients only 22 in which he thought pneumothorax was indicated, and among these he succeeded only in six cases to completely collapse the lung, in 11 adhesions prevented the creation of a complete pneumothorax, and three refused to submit to the treatment. J. Courmont[27] found among 352 patients only 31 were suitable, and among 110 apparently suitable cases only in 32 per cent. could Zink[28] produce complete pulmonary collapse and in 24 per cent. he failed to enter the pleura altogether because of pleural adhesions.

In our 22 suitable patients we failed in seven cases to partially or completely collapse the lung. Saugman found that in 30 per cent. of the selected cases adhesions prevented the entry of gas into the pleural cavity. Even with Brauer's method the proportion of failures exceeds 25 per cent. It must, however, be mentioned here that while in most cases complete collapse is best, a partial pneumothorax at times serves a good purpose, and many writers report excellent results when only creating one or more gas pockets in the pleura, and in two of my cases the improvement was remarkable under such conditions. Von Adelung[15] even practises partial inflation of the two pleuræ *simultaneously* in some bilateral cases, and he says that the results have thus far been apparently beneficial. To my mind this improvement can only be seen in chronic cases of phthisis in which the cavities have been surrounded by stiff walls of connective tissue, and which do not secrete any more. Exquisite amphoric breath-sounds are heard over such cavities, but no râles. The excavations are not the cause of the general symptoms which disable the patient, but the more acute patches of infiltration in other parts of the lung are responsible for the fever, night-sweats, cough, etc. Compressing these parts, we may achieve good results. In these cases we hardly ever achieve a cure with pneumothorax, because the cavity cannot cicatrize or contract, owing to the stiffness of its walls which, together with the pleural adhesions, prevent its collapse by the gas pressure. But they may be greatly relieved by a pneumothorax.

Technique.—The technique of the induction of a pneumothorax is simple, but not devoid of danger and even fatal accident. Of the two methods in vogue at present the one originally recommended by Forlanini and by Murphy is the most commonly practised in this country and in Europe. Brauer's method consists in incising the chest wall, dissecting down to the pleura by cutting through the fascia, and separating the intercostal muscles with a blunt instrument in the direction of their fibers. When the parietal pleura is exposed, it is punctured with a blunt needle or cannula and the gas is allowed to flow in by aspiration of the pleural cavity or by pressure when indicated. This method has failed to gain many adherents for various reasons; but few patients want to submit to a cutting operation. Then there is an obvious danger of sepsis which may, of course, be avoided by the usual methods. I have found no reason for resorting to the bloody operation and feel confident that if this was the only available method of inducing a pneumothorax we would find very few patients willing to submit.

The Forlanini and Murphy method is bloodless and painless. It consists in a simple puncture of the chest wall with an especially constructed hollow needle which is connected with a gas reservoir and a water manometer through a T-shaped tube. When the lumen of the needle punctures the costal pleura the gas is allowed to flow into the pleural cavity by the suction or negative pressure in that cavity as well as by some positive pressure which must at times be used at the gas reservoir.

Simple as this operation appears to be, there are certain difficulties to be overcome and dangers to be avoided. The main difficulty is to pass the needle as far as the costal pleura, puncture it, and avoid penetrating the visceral pleura and the lung. The dangers are mainly in allowing the gas to flow in into places other than the pleural cavity, especially into a blood vessel thus causing gas embolism which while not invariably fatal, yet it is sufficiently menacing to be dreaded by all who are doing this sort of operation.

Apparatus.—To avoid this accident various forms of apparatus have been invented during the past six years. As is usual, they are all based on one main principle—the manometer which has been introduced by Saugman. Each apparatus consists

Fig. 6.—Incomplete pneumothorax for cavity in the lower part of the upper lobe of the left lung. Dense pleural adhesions prevented the collapse of the cavity, and the general symptoms have not materially been influenced.

primarily of two graduated bottles connected by tubing, one containing the gas to be inflated and the other some fluid, so that the fluid flows from its container into the other bottle, displacing the gas which is sucked or pressed into the pleural cavity through a tube and an especially constructed needle. This last-mentioned tube is T-shaped or provided with a three-way stopcock, of which one limb communicates with the gas bottle, the second with the needle, and the third with the manometer. At any moment during the operation we can open or close the tube leading to the manometer or the gas reservoir.

As I said all the instruments for the induction of a pneumothorax are constructed on this simple principle, but it is amazing how some have succeeded in complicating it by adding various attachments which make them unwieldy and easily disordered. The experience that a machine in order to be most useful must be of the simplest construction, consistent with efficiency, holds good here. At the Montefiore Home we have been using Forlanini's apparatus as modified by Saugman and von Muralt, and also the Robinson apparatus. The latter has been used more often than the former because of its simplicity.

The Manometer.—The entire safety of the operation lies in the manometer, which has been called by von Adelung the heart of the apparatus. While the needle passes through the skin, subcutaneous tissue, muscles, and fascia before piercing the costal pleura, the manometer records atmospheric pressure, but as soon as it enters the pleural cavity the air in the connecting tube becomes rarified because the vacuum in the pleural cavity aspirates its air content, and the fluid in the closed limb of the manometer is sucked up toward the needle, *i.e.* from the open into the closed limb and a distinct difference in the levels of the fluid is evident. Moreover, when the lumen of the needle is really in the pleural cavity the respiratory movements of the lung are recorded in the manometer which shows distinct oscillations of the levels of its fluid.

This explanation of the work of the manometer, which is found in most works on the subject, is unsatisfactory. The fact is that normally there is no pleural cavity at all because the parietal and visceral pleuræ lie tightly, one on another; nor can we speak of negative pressure between the two pleural sheets, because the word "pressure" is here used in the sense of gas pressure which can be measured with a manometer; but such a negative pressure does not exist between the two pleural sheets. The manometric readings when the lumen of the needle is in the pleura are explained better by Brauer,[3] Piéry,[22] and Moritz[23] in the following fashion: The lung must be considered as an organ fixed at its root and kept in a state of equilibrium by the pressure of the atmospheric air within the air passages and by the elastic tension of its tissues. There is a constant tension of the lung from the roots to the periphery at the thoracic walls. The force of this traction is equal to the absolute elastic tension in the given direction, minus the atmospheric pressure which prevails within the air passages and so prevents its collapse or retraction from the periphery to the hilus. The intrapleural pressure therefore never differs much from the atmospheric pressure, as has been shown by W. Parry Morgan,[20] and in consequence any gas drawn into the cavity will not be appreciably rarified. The volume of gas which will have passed from the connecting tube into the pleural cavity will be practically equal to the amount of fluid which will have passed from the open to the closed limb of the manometer. This volume would, when the negative pressure stands at 15 cm. of fluid in a manometer tube of 0.3 cm. bore measure less than 1 c.c.

This is enough to separate the sheets of the pleura if there are no adhesions. But owing to the elastic tension of the lung and the atmospheric pressure within the air passages, there is actually shown a negative pressure in the manometer. A little reflection will explain why this negative pressure will be stronger during inspiration because of the greater distance at that period between the root and the periphery, and less during expiration. With the increase in the quantity of gas introduced into the pleural cavity the tension of the lung will obviously decrease and with it the negative pressure, until finally a point is reached when the pressure in the gas-containing pleural cavity is 0 and later even becoming positive.

Bearing in mind these simple principles of the manometer we are in a position to guard against the most important of the accidents which are liable to happen during the operation. In patients with pleural cavities free from adhesions ordinary and careful attention to the manometer will suffice to guard against mishaps. The manometer shows conclusively whether the lumen of the needle is in the pleural cavity or not. It also gives reliable information as to the state of the pleural cavity, with particular reference to adhesions, showing whether they are dense and extensive, or of slight extent and may be separated and broken up by an increase in the intrapleural pressure with the gas. During the course of the treatment we are able to ascertain, with the aid of the manometer, whether the nitrogen has been absorbed and refill is necessary; whether the lung has been completely immobilized or has remained expansile. When it is found that the intrapleural pressure increases and this can not be attributed to excessive gas insufflations, the manometer indicates pleural effusion. The difficulties in cases with pleural adhesions will be discussed later on.

The Selection of the Point for Injection.—The first inflation must be carefully done and it is important to select a point to introduce the needle where no adhesions are likely to be encountered. Bearing in mind the anatomy of the chest and its viscera it is evident that the ideal point is along the anterior or posterior axillary lines, especially at the ninth intercostal space posteriorly for apical lesions, or in the third intercostal space just outside the mammillary line for lesions of the lower lobes. Of course, when we are free to choose, areas covered with thick muscles or the mammary gland in women are to be avoided. But we are not always free to choose, and any point must serve our purpose when the elective places are not available because of adhesions. It must also be emphasized that it is very difficult, often impossible, to avoid pleural adhesions with all the means of diagnosis at present at our command.

We are generally guided by the following principles: The chest is punctured as far away from the main pulmonary lesion as possible because pleural adhesions are most likely to be encountered over the diseased lung and, what is more important, while puncturing the lung is ordinarily harmless, in such places the needle may, however, penetrate cavities and produce a pyothorax. But adhesions are found everywhere and often where we least expect them. Physical diagnosis is apt to prove misleading and the fluoroscope and radiography just as often may fail to reveal them. I have met with cases in which the radiogram showed all the conventional signs of pleural adhesions but puncture revealed a free pleura and complete collapse was easily obtained with three or four inflations. More often yet the radiogram shows a clear picture and it is concluded that the pleura is free, but puncture shows conclusively that there are adhesions.

Forlanini[2] is guided by tidal percussion of the margins of the lung, especially at the base. When he finds that the base line in the axilla shifts between 10 and 12 cm. during extreme inspiration, as compared with extreme expiration, he is convinced that the pleura is free. Good mobility of the lung margins is the most important sign of freedom from pleural adhesions, according to Forlanini, but he adds that immobility is not a sure sign of such adhesions and of obliteration of the pleural cavity. There are cases of extensive hepatization of the lung in which the mobility of the lung margin is defective or absent, yet the pleural cavity is free. Robinson and Floyd also consider percussion the

most reliable guide and they say that the area presenting a note nearest approaching the normal resonance is most likely to be free of adhesions, while von Adelung seeks an area which is resonant and yields breath-sounds.

It appears that the most reliable means of ascertaining whether or not the pleura is free is the attempt to enter it with the needle connected with a manometer. When the first puncture does not yield negative pressure in the manometer, a very frequent occurrence, so that when one enters successfully with the first puncture he considers himself lucky, another attempt is made at another point. I have made in one case four punctures before succeeding to enter the pleural cavity and in another twelve before giving up as not suitable for the treatment. Forlanini made fifteen punctures in one case before he finally succeeded.

The skin at the site selected for puncture is painted with tincture of iodine and the excess is washed away with alcohol. It is then frozen with ethyl chloride and an injection of one-third of a grain of novocaine or cocaine in 1:2000 adrenalin solution is made. At first the skin is infiltrated, then a few drops are injected into the intercostal mus-

Fig. 7.—Radiogram of a chest in which the physical signs and x-ray indicated the absence of adhesions, yet all efforts to induce a pneumothorax in the left side have failed, and after twelve punctures it was decided to discontinue the treatment.

cles, and finally into the pleura. The latter must not be neglected: it appears to be the only known way of preventing pleural shock of which we shall speak later on.

Thoracocentesis.—The selected intercostal space is carefully palpated with the index and middle fingers of the left hand to make sure of avoiding a rib when thrusting the needle into the chest wall. If a blunt needle is used the skin is first punctured with a tenotome. The needle is inserted and pushed slowly forward passing through the subcutaneous tissue, fascia, and muscles. While the latter are passed the needle goes smoothly, but when the endothoracic fascia is reached a certain amount of resistance is encountered, which is characteristic to the experienced hand. A similar, but stronger, resistance is felt when the pleura is passed and it is often difficult to decide with confidence as to whether it was the fascia or pleura which was punctured. The manometer is the only means at our command to make sure of where the lumen of the needle is.

How far the needle is to be pushed depends on the thickness of the chest wall of the given patient. All efforts are to be made to avoid penetrating the lung. While in the vast majority of cases this is entirely harmless, on rare occasions it may prove a serious and even a fatal accident. We may induce a spontaneous pneumothorax, an accident which occurs more often than is generally appreciated.

The usual length of the needle, Floyd's modification of Brauer's, is 5 to 6 cm. This is excessive and Saugman's needle which is only 3 cm. long is at present used by me exclusively. Saugman noted in 100 cases in which he succeeded in inducing pneumothorax the depth to which it was necessary to penetrate the chest wall as far as the pleura and in none of them was it deeper than 3 cm.; in the vast majority it was only between 1.5 and 2.5 cm.; in some less than 1.5 and in one even less than 1 cm.

Technique of Insufflation.—As soon as the lumen of the needle penetrates the costal pleura and there are no adhesions at the point of penetration, the tube leading to the manometer is opened and the fluid in the closed limb is seen to be sucked up. In some cases the suction is so pronounced that the fluid shoots up to the upper end of the tube and care must be taken that it is not aspirated into the pleura. Usually it is elevated between 1 and 6 cm. and oscillates. The patient is told to take a deep breath and it will be observed that during inspiration the negative pressure is more pronounced than during expiration. This oscillation is the only reliable indication that the lumen of the needle is in the pleural cavity, but at times there are observed slight oscillations when the needle reaches the costal pleura before puncturing it owing to the respiratory movements of the lung. But these oscillations rarely exceed 1 cm. and must not mislead us. Only when the negative pressure exceeds 3 cm. may we venture to let in the gas, and beginners should not do it with less than 5 or 6 cm. negative pressure.

With the assurance that the needle is in the pleural cavity the manometer is closed, the tube leading to the gas reservoir is opened, and nitrogen allowed to flow in by aspiration or pressure when necessary. After 100 c.c. of gas has entered, the manometer is again consulted, and if still showing negative pressure, another 100 c.c. is allowed to flow in. It has been my habit never to exceed 300 c.c. of nitrogen during the first operation, although many do not hesitate to introduce two and even three times as much, and some even attempt to secure complete collapse of the lung during the first operation. Murphy advises the introduction of 200 cu. in. (3,000 c.c.) at the first operation, while Forlanini now advises only 200 to 300 c.c. Clinical experience seems to favor smaller quantities as safer and many unpleasant, often dangerous, symptoms are thus avoided. To change quickly the relations of the thoracic viscera is dangerous. Moreover, when adhesions are present they may be torn apart forcibly and cause trouble. When extensive and dense adhesions are present it is often impossible to introduce more than 100 or 200 c.c. of gas and the chances of securing finally a complete collapse of the lung are rather slim.

On the completion of the operation the needle is quickly withdrawn and the index finger of the left hand placed over the point of the puncture and some pressure applied with a view of preventing cutaneous emphysema. Finally the small wound is sealed with some cotton and collodium and the patient is warned against coughing, which he is to avoid as far as is within his control. I find a dose of morphine or codeine is useful for this purpose.

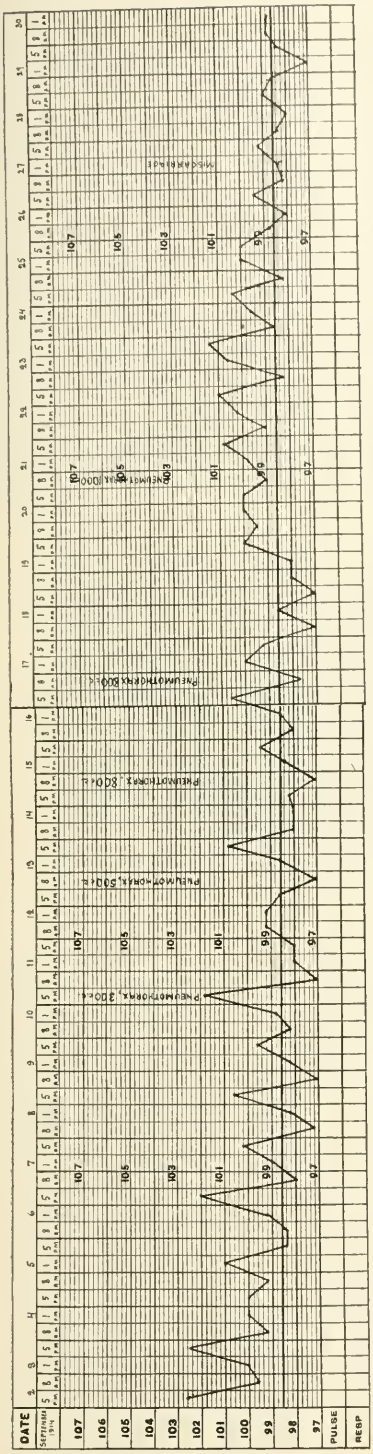

Chart I.—Temperature curve of the patient whose radiogram is shown in Fig. 4. The temperature has been around normal since the lung has been completely collapsed

It has been my rule to send the patient to bed for twenty-four hours after the first operation irrespective of his general condition.

Technique of Refilling.—The introduction of a few hundred cubic centimeters of nitrogen does not collapse nor immobilize the lung. This must be accomplished gradually by further inflations. In cases with free pleuræ this is a simple matter considering that a pocket with gas has been created already and the needle can be introduced easily into it. For this reason it is best to do the second inflation in the neighborhood where the first puncture was successfully made, so that it enters the gas pocket, and only exceptionally is another place chosen. In the latter case we are guided by the same principles as during the primary puncture. One thing is to be remembered: the manometer is to be always consulted before the gas reservoir is opened and in case no respiratory oscillations are seen, the stillet is to be inserted into the needle on the assumption that the lumen may be clogged, which is often the case. If no oscillations are even then observed, the needle is to be withdrawn and reinserted in another place. Accidents have happened during later inflation just as during primary operations.

The quantity of nitrogen introduced during refills depends on the case. My way has been to introduce between 300 and 600 c.c. at the second and 800 to 1,200 at the third operation, provided the patient bears it well. But when I find embarrassment of the circulation, dyspnea, or pain in the chest, I proceed slower and am satisfied with 300 c.c. given every other day till complete collapse is attained in two or three weeks.

We are also to be guided by the final pressure after each inflation. In many cases we get positive pressure after several hundred cubic centimeters of nitrogen have been introduced, although there is no complete collapse of the lung. We often meet with cases in which the gas opens but a small pocket in the pleura and when this is filled the negative pressure decreases or vanishes. When oscillations are good the pressure may be increased guardedly, consulting the manometer after each 50 or 100 c.c. have entered. Saugman, whose experience is unexcelled, found that if gas does not pass with 10 to 15 cm. water pressure the case may be given up, because higher pressure will meet with failure.

At times it is noted that during a refill the pressure suddenly sinks. This is an indication that some adhesions have yielded or, which is fortunately exceedingly rare, that the lung has ruptured and the gas escapes from the pleura into a bronchus. This may occur when the nitrogen is introduced under high pressure and the patient coughs vigorously.

My experience coincides with that of Saugman to the effect that it is best that during the first few fillings the final pressure should not exceed 0.5 to 2 or 4 cm. of positive manometric pressure. The condition of the patient as well as his reaction during the succeeding few days should, however, be our guide. We must always watch whether our aim is not attained with a low pressure and in many cases ½ to 1 cm. above zero is sufficient. Forcible inflations involve dislocation of the medastinum and injury to the other lung. We must bear in mind that it is not always imperative to compress the lung. In most cases affording rest to that organ by immobilization is sufficient to give relief, and this

can be attained without high intrapleural pressure. But in case the patient is not improving, his temperature, cough, expectoration, etc., are not influenced favorably, the pressure is carefully and guardedly increased. A final pressure of 10 to 15 cm. of water is too high, though many authors state that they have resorted to it in some cases. Of course, as a rule, the gas is quickly absorbed and within a few days the pressure drops so that the embarrassment of the respiration and circulation is ameliorated. The great problem are the cases in which only an incomplete pneumothorax has been created and the stiff, unyielding walls of cavities, or dense pleural adhesions, prevent the compression of the part of the lung which we aim to collapse. Saugman and Forlanini have not hesitated to increase the pressure in these cases to 30 and even 40 cm., and they were occasionally rewarded by attaining finally a complete pneumothorax.

After complete collapse of the lung has taken place the frequency of the refillings is diminished. In some patients gas is absorbed slower than in others and we are unable to say in advance who is well able to leave their bed immediately after the operation and attend to their affairs. The slight difficulty in breathing, seen in some cases at that time, is usually objective, the patient protesting that he feels well although he evidently suffers from air hunger of some degree. But even this disappears within a couple of days, as has already been mentioned. Only in rare instances, when the gas separates adhesions by high pressure, does the patient complain of pains in the chest which are, as a rule, trifling.

In febrile patients the effects of the pneumothorax are usually striking, especially when complete collapse of the lung is attained. The fever disappears and in successful cases does not return unless there is some complication. The temperature charts (Charts II and III) show distinctly the effects of collapse of the lung on the temperature. One is the case of a pregnant woman who, before admission to the hospital, had continuous fever for several weeks reaching 103° and 104° F. during afternoons. During the first week at the hospital it was remittent and accompanied by nightsweats, which were exhausting. But since the first infla-

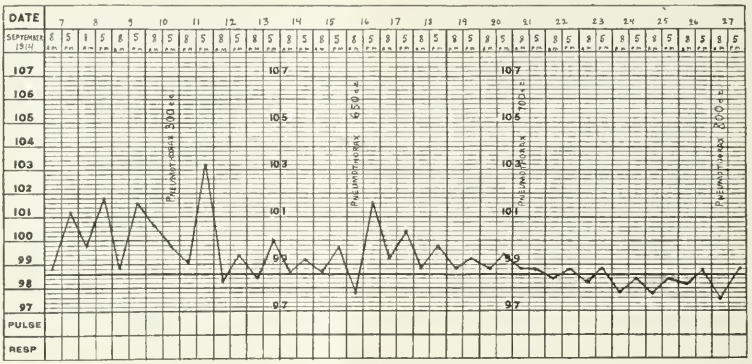

Chart II.—Showing the influence of therapeutic pneumothorax on the temperature.

likely to need frequent refills and who is likely to need infrequent refills. It seems that those walking around are absorbing the gas sooner than those who remain in bed. Primarily the guides for the necessity for refills are the general condition of the patient and secondarily the findings on physical examination. An elevation of the temperature, if not due to an impending or actual pleural effusion, is often removed by a refill. The same is true of cough and expectoration. In those who had the lung completely collapsed there was a complete absence of breath-sounds and adventitious sounds; a return of these is an indication that refilling is necessary. The fluoroscope is, however, the best guide. I want to repeat, however, that the dyspnea and tachycardia, which are often caused by excessive pressure in the pleural cavity, are to be guarded against.

Symptoms.—The acute and urgent symptoms of spontaneous pneumothorax are never seen in the artificially created pneumothorax, excepting, of course, when the lung is penetrated and the spontaneous variety complicates matters. The pain, dyspnea, cyanosis, and collapse are never encountered. In fact the majority of patients who have overcome the fear for the operation are ready and tion of 300 c.c. of nitrogen on September 10, there was an evident tendency on the part of the temperature to reach the normal limits, and since the 26th of September it has been normal. Her general condition has improved, she ceased coughing, expectorating, regained her strength, and feels well. even a miscarriage on the 27th of September has passed an uneventful course, she remaining in bed for one week, but the temperature, pulse, etc., were normal.

In some cases it is noted that the fever increases 1° to 3° F. for twenty-four hours after each insuflation (Chart II) just as is the case with the reaction after an injection of tuberculin. This is probably caused by increased toxic absorption, owing to the compression of the diseased lung. In case an increase in the temperature, lasting several days, is noted during the treatment we may look for some unpleasant complications, especially a pleural effusion. When the pneumothorax does not reduce the temperature we may consider the treatment a failure in the particular case. With the disappearance of the fever the nightsweats vanish and this gives the patient great relief.

The appetite improves in all successful cases, and with this the lost strength is gradually regained,

and the languor, which is such a strong clinical feature of the disease, is replaced by a feeling of well-being. In short the pessimistic attitude is replaced by a hopeful feeling. The digestive organs often show marked improvement in function and in some cases the diarrhea is favorably influenced.

It is noteworthy that in spite of this improvement in the general condition of the patients the gain in weight is not a constant phenomenon in artificial pneumothorax. Of the 15 successful cases at the Montefiore Home only 2 gained, while the rest either remained stationary in weight or even lost. This has been observed by nearly all writers on the subject and has been attributed to the diminution in the oxidation area owing to the elimination of one lung from the respiratory function and therefore there is a diminution in storing up flesh. "People do not eat only with the digestive apparatus, but, in the final analysis, also with their lungs," says Jessen[23] in this connection. Saugman says that as long as the general condition of the patient is good and the loss of weight inconsiderable, it should not trouble us. When, however, the loss of weight is considerable and general symptoms, such as fever, sweats, anorexia, etc., make their appearance, we may first try to reduce the pressure in the thorax, and if this does not ameliorate the condition, the treatment may have to be given up.

Great relief is usually obtained in patients who suffer from severe coughing spells which keep them awake during the night. In all my cases the cough disappeared and often with it the insomnia. This is especially true of unilateral cases in which a large cavity is emptied by compression. After the first three or four inflations it is constantly observed that the amount of sputum expectorated is augmented because the pressure exerted by the gas empties cavities and bronchi of their contents. After the lung has completely collapsed, or the cavities have been emptied in partial pneumothorax, the quantity of sputum diminishes and in unilateral cases, expectoration ceases altogether. In many cases tubercle bacilli are not found in the sputum after the lung has been compressed for two months.

More striking than the improvement in the general condition is the cessation of hemoptysis when the first inflation is made during a hemorrhage and in hemorrhagic phthisis in which the patient is in constant dread lest the hemoptysis recur, we can assure him that he is safe in this regard. In hemoptysis pneumothorax acts as a hemostatic like the tampon in uterine hemorrhage. In one of my cases there occurred a mild hemorrhage during the treatment, and I was satisfied that the blood came from the untreated lung. In three cases in which the pneumothorax was induced for the relief of copious hemorrhage, we succeeded in two to promptly check the bleeding.

In many, though not in all cases, there occurs some dyspnea during the operation or immediately after. But this is, as a rule, transitory. In fact, when the dyspnea is due to fever and toxemia it disappears after the induction of a pneumothorax. If excessive pressure is permitted to prevail in the treated pleura dyspnea is likely to occur which is usually transitory. The absence of dyspnea despite the cutting of the breathing area in nearly one-half is not surprising because, as was already stated, in pneumothorax and in pleural effusions a reduction of 66 per cent. of the respiratory area does not materially alter pulmonary ventilation, nor the chemistry of respiration, provided the patient is at rest. None of my cases showed any signs of dyspnea as long as they kept at rest, while some showed signs of respiratory embarrassment on exertion. But the dyspnea was usually objective, the patient protesting that he was not short of breath, although it could be seen that the respiration was rapid.

CHART III.—Showing the influence of therapeutic pneumothorax on the temperature.

Physical Signs.—Recalling the physical diagnosis of spontaneous pneumothorax as given in text books we are surprised that most cases of artificial pneumothorax do not show many of the supposedly pathognomonic signs. Thus, tympany is not a constant sign, and in some cases the treated hemithorax is simply hyperresonant and, in contrast with the untreated side, only shows a tympanitic overnote, because of the vicarious emphysema in the latter, which is hyperresonant or even tympanitic on percussion. It is hazardous to diagnose pneumothorax by signs obtained on percussion alone. The only feature that may give a clue is displacement of the heart, especially in cases of left-sided pneumothorax in which even a small amount of gas may shift the heart to the right.

On auscultation we find in cases with complete collapse of the lung total absence of breath-sounds, as well as of any râles which may have been audible before the gas was introduced. In these cases we may be guided by the auscultatory findings as

to the necessity for refilling. When the breath-sounds return it means that quite some portion of the gas has been absorbed and must be replaced at once. In cases in which the lung has been collapsed but large bronchi have remained active we may hear distinct and exquisite amphoric breathing or distant metallic breath sounds, which shows that the teachings of some text books to the effect that the amphoric phenomena in spontaneous pneumothorax are due to bronchopleural fistulæ is erroneous.

It is evidently due to sounds originating in the bronchi which reverberate in the air-filled pleural cavity. The progress of the pneumothorax can usually be followed by noting the increase in the area of the thoracic surface over which there is either absence of respiratory sounds or amphoric breathing after each filling, till finally the complete lung is collapsed and all breath and adventitious sounds disappear.

Complications.—Not all cases of induced pneumothorax run a smooth course during the period of treatment. Complications may arise during the operation or immediately after and while the patient goes around with a collapsed lung. Of the former collapse, pleural shock or pleural eclampsia, pains in the chest, and subcutaneous emphysema are worthy of consideration; of the latter pleural effusion is the most important.

Pleural shock may be of various degrees. The mild forms manifest merely an increase in the rate of the pulse and respiration, pallor, dyspnea, etc., which pass within a few minutes or an hour. I have met with it several times; in one patient it occurred consecutively during the first four inflations and I am inclined to attribute it in a great measure to his fear for the operation. In one of my cases the shock was quite severe, even alarming, yet it passed away within half an hour. Several authors have reported fatal cases. The etiology, especially of the fatal cases is not clear. Forlanini, Saugman, and others are inclined to attribute it to reflex spasm of the cerebral or cardiac blood vessels. It has been observed that thoracocentesis for any purpose may cause collapse or even death on very rare occasions. Brauer is inclined to attribute the symptoms of shock to gas embolism in most cases and says that the fact that it is usually transitory does not exclude gas embolism. But pleural shock may occur without any gas inflations. Lyon[72] mentions a case occurring while injecting novocaine into the pleura.

That this accident is comparatively rare is evident from Forlanini's figures to the effect that operating on 134 patients, not including those in which he failed to produce a pneumothorax, and making more than 10,000 operations, he met with pleural shock only 12 times. Among 150 inflations made at the Montefiore Home we observed it but once sufficiently severe to cause some alarm.

Gas Embolism.—When the manometer is not consulted properly, it is said that at times even when the most careful technique is followed, gas may enter a blood vessel and be carried away to any part of the body and produce an embolism. Usually one of the pulmonary veins is entered, and it is well known that negative pressure prevails in these vessels. Brauer maintains that one of the veins around an infiltrated area of lung tissue or pleural adhesions may be penetrated by the needle and gas introduced into the circulation. The nitrogen is carried into the left heart, then into the aorta, whence it may travel into the coronary arteries or the cerebral vessels. Experimental researches have not been uniformly confirmatory of this theory, and clinically the symptoms of embolism have been observed in some cases even when no nitrogen was allowed to enter through the needle—merely after introducing the needle. Wolff-Eisner,[73] while agreeing that in most cases it is due to gas embolism, says that there are some in which thrombi are responsible for the symptoms observed. They are derived from the vessels around or within the pulmonary or pleural lesion and dislodged by the needle. However, it must be emphasized that symptoms of gas embolism are not exclusively encountered in the primary operations but have been met with during refills.

The symptoms are collapse, inequality of the pupils, hemiplegia, etc. In some rare cases death has occurred without warning. I have been fortunate in not having met with a single case of this kind in my practice. Of course, prophylaxis is to be the chief aim while operating, and one who does not permit the gas to flow into the chest without considerable oscillations of the manometric column is hardly likely to meet with a case.

Pains in the chest are felt by the patient occasionally during the operation. At times while introducing the needle as far as the costal pleura and before penetrating it exquisite pains are felt which promptly disappear as soon as the pleura is punctured. This can be prevented by proper anesthesia of the pleura with novocaine or cocaine. Very often after the introduction of the gas pains are felt in the chest for twenty-four hours, due to breaking up of adhesions, especially when high pressure is applied. They are not at all unbearable and need no treatment. Abdominal pains may result from lowering of the diaphragm by the intrapleural gas pressure, but this also is transitory and needs no treatment.

Spontaneous pneumothorax may occur when the needle lacerates the visceral pleura, or when a superficial lesion or cavity of the lung breaks through after the pleural sheets are separated by the gas. Forlanini has met with nine cases of this kind; Floyd mentions it. It has occurred in one of my cases: The patient was given but 150 c.c. of nitrogen into the left pleura during the first operation and while examining him the next day, complete collapse of the left lung was discovered with displacement of mediastinum to the right. The symptoms were those of a mild case of spontaneous pneumothorax, and orthopnea was quite marked for about two weeks, but the shock and collapse were lacking. He made an uneventful recovery. Of course, when this complication is due to the entry of the needle into a cavity or even a caseating part of the lung, pyothorax with its concomitants are likely to be the result. In fact, such cases have been reported.

According to W. Parry Morgan, "spontaneous" pneumothorax is more often produced while inducing an artificial pneumothorax than is generally appreciated. This is confirmed by the occasional cases met with in which the treatment is abandoned after a futile trial to introduce gas into the pleura, and a collapsed lung is then discovered. Again, a radiograph of the chest taken after the first operation usually shows evidence of more gas in the pleural cavity than has been introduced from the reservoir. While it is common experience of those using the method that gas can be detected after 200 or 300 c.c. have been introduced, it has been Morgan's experience that if the visceral pleura is not injured the gas cannot be detected until con-

siderable more than 300 or 400 c.c. have been introduced. He concludes that when a pneumothorax is visible in the fluoroscope after introducing 300 or 400 c.c. of nitrogen, we have justification for the conclusion that radiographic demonstration of a pneumothorax after the introduction of such a quantity of gas is achieved only by this being largely supplemented by leakage from the lung.

Subcutaneous Emphysema.—The infiltration of gas into the subcutaneous tissues of the thoracic wall around the point of the puncture is very frequently observed, especially in those operated upon by the Brauer method. In the vast majority of cases it is due to the high pressure of the gas in the pleural cavity, supplemented by cough, and the nitrogen works its way along the tract of puncture. It is readily recognized by the crepitation elicited on palpation and is of little significance,—passing away spontaneously within three or four days or at most a week, and further inflations are not contraindicated while it is present. It may be prevented by using thin needles and warning the patient against coughing, or administering some sedative like codeine immediately after the operation. It has occurred in about one-half of my cases after the first or second operation and rarely after later inflations.

Of more serious import is emphysema of the deep tissues of the thorax, which fortunately occurs only rarely and may be avoided by careful technique. It is usually due to the injection of nitrogen into the subpleural tissues before the lumen of the needle has penetrated the costal pleura. As was shown by Brauer, Spengler, and others, deep emphysema may also be due to leakage from the pleural cavity through the wound made by the needle, the gas being pressed by the intrapleural pressure or the respiratory movements especially during cough, into the extrapleural tissues. Saugman is of the opinion that this may even occur without excessive intrapleural pressure although the latter enhances the chances of its occurrence. The gas works its way along the paths of the vessels to the posterior mediastinum and thence along the vessels and trachea up to the neck, where we may discover it by the crepitation along its anterior aspect. It is noteworthy that it is often felt earlier on the untreated side of the neck, which Saugman believes is due to posture. Rarely the emphysema may extend along the vessels to the face, shoulder, arm, and forearm. It may be severe enough to cause dysphagia and pain wherever it occurs. But the ultimate outcome is always favorable—it disappears within a few days or a week. It has occurred in two of my cases and, barring the little inconvenience it caused them, it was of no significance. Saugman, who had more experience with deep emphysema, states that in the patients it occurs there are but few chances of inducing a complete pneumothorax because of the gas leakage.

With abdominal emphysema, which has been described by several authors, I have no experience. It may occur when the needle is inserted along the lower margin of the chest and the diaphragm happens to be unduly high, which is not unusual in pulmonary tuberculosis. The lumen of the needle may then reach the peritoneum, between the diaphragm and the stomach or liver. It is to be remembered that there also the manometer will show negative pressure, oscillating with the respiratory movements. Saugman points out that it is difficult to distinguish these oscillations from those seen when the needle is in the pleural cavity, but if it is carefully watched it will be observed that when the needle is in the pleural cavity the negative pressure is stronger during inspiration, and the reverse is true when the lumen of the needle is in the peritoneal cavity.

Pleural Effusions.—The most frequent and serious complication of artificial pneumothorax is pleural effusion in the course of the treatment. Its frequency varies with the different reports by various authors. Some report as high as 50 per cent. of cases, while others have met with it less frequently. Some are inclined to attribute it to "colds" or to "rheumatism," etiological factors which are open to question. Others have stated that it is usually due to infection during the operation and maintain that when asepsis is rigorously observed effusions are rare, which does not hold, because effusions have been met by the most careful of operators. Floyd says that where injections are very frequent and small amounts of nitrogen are given at a time it is more likely to occur than where the interval is of some duration. Faginoli[3] considers the nitrogen as a foreign body which irritates the serous surface of the pleura, predisposing it to disease. It becomes a lucus minoris resistentiæ, and inflammation occurs more easily than in ordinary cases of phthisis. Klemperer's explanation is more plausible: Disease processes which reach the surface of the lung and the visceral pleura cause adhesions in patients with normally superimposed pleural sheets, but in pneumothorax with separated pleural sheets exudative inflammations are the result. Rupture of adhesions which lay bare tubercular foci in the pleura may also be instrumental in infecting the complete serous surface. The fact that the fluid usually contains lymphocytes and is pathogenic to animals is conclusive proof of the tuberculous origin of these effusions.

The diagnosis is difficult at the onset. In most cases there is a rise in temperature, though at times it may pass afebrile; but there is no chill. The fever is hectic and may reach 103° F. and higher. There is also a rise in the intrapleural pressure which cannot be accounted for by the inflations, and the manometric oscillations are diminished. Grocco's triangle can be made out when the effusion is considerable, though Faginoli says that it is always absent. Small effusions are often very difficult to diagnosticate, and even the fluoroscope may fail to reveal them. They are especially difficult to be discerned in radiograms which have been taken with the patient reclining, for obvious reasons. When more or less copious the usual signs of pleural effusion are present plus the succussion sound and the splash, which are at times annoying to the patient.

The effects of the effusion depend on whether they are of a toxic nature or not. In the former case there is prolonged fever of a hectic type. Simple effusions, as has been pointed out by von Muralt, are rather a salutary phenomenon and may have a good effect on the general and local condition of the patient by the antibodies it produces. Faginoli does not agree with this view and says that in the end effusions interfere more or less with the favorable outcome of the case. Saugman also states that in the majority of cases it is a rather disagreeable complication, which is in agreement with my experience. The patients who have had effusions have not done as well as those without this complication.

As long as there is no fever and no cardiac em-

barrassment the effusion should not be interfered with, because it keeps the lung collapsed, and this is just what we aim with the treatment. But in cases in which the fever is high it may be necessary to withdraw part of the fluid and replace it with nitrogen. In one case I have applied autoserotherapy—withdrawing 10 c.c. of fluid and reinjecting it subcutaneously, and am under the impression that it enhanced absorption. We must always watch these exudates. In case they are absorbed too rapidly, the lung re-expands and may form adhesions, thus preventing its further collapse by the gas inflations.

I have had but one case of pyopneumothorax in my series, and another one which was inflated originally in another institution. The latter succumbed after a prolonged illness, and the former is not doing well.

Extension of the disease to the other lung is perhaps the most disheartening complication during the treatment. It has been stated that it may be caused by an attempt to collapse the more affected lung too quickly; the purulent matter is squeezed out rapidly, and it travels along the bronchi to the other side of the chest, producing pus embolisms of the bronchi. It has also been attributed to excessive pressure in the pneumothorax. It has occurred in two of my cases, and in neither could I attribute it to these causes. In one of my cases there was a hemorrhage from the untreated lung, but it soon ceased. There have been reported cases in which one side of the chest was treated by a pneumothorax and the lesion was cured, but subsequently a new lesion flared up in the opposite lung, which was also treated by a pneumothorax. This indicates that the collapse and compression of a lung do not necessarily impair its function permanently.

Duration of the Treatment.—The question how long the pneumothorax must be maintained in order to achieve a cure can not be answered definitely; no rules can be laid down which will apply to all cases. In fact, considering that the method of treatment has been applied such a short time, there are few who have had many cases under observation for six to ten years, and even they have not agreed as to the usual duration of treatment of a successful case. The following principles are based on the experiences reported by Forlanini, Brauer and Saugman, who have had patients under their care for many years, as well as on my own observations, which have not yet extended for a sufficient time to give definite conclusions.

It appears that we cannot count on less than two years in the most favorable cases, although some have reported success within one year—the pneumothorax was allowed to be absorbed and there occurred no relapse of the disease. But these cases are few. To my mind, the most difficult problem is to determine when the healing process has been completed, so that if the lung is permitted to re-expand no active lesion will remain to flare up again by the respiratory movements. This, however, is difficult and, I believe, impossible to determine with any chance of precision as long as there is complete collapse of the lung, and the general condition of the patient is good because of the collapse. Moreover, if we allow the pneumothorax to be absorbed too early there may not only be a relapse of the disease, but experience has shown that the pleural sheets are likely to adhere and the fibrous bands prevent the formation of a new pneumothorax if we find that this is indicated.

It is for this reason that whenever we decide to discontinue the treatment we must watch carefully the patient while the gas is slowly being absorbed and if some symptoms appear, such as fever, cough, expectoration, anorexia, tachycardia, etc., we must at once reinflate the pleura. Forlanini says that many patients require a pneumothorax "forever," which is undoubtedly true, and most authors who had experience with this method of treatment for many years, and had opportunities to observe their cases for long periods of time, agree with him.

Saugman, who has treated with artificial pneumothorax numerous cases and observed them for many years, says that when only a partial pneumothorax has been created which, however, has had a good effect on the symptomatology of the disease the treatment must be continued for at least two years, often for a longer period, according to clinical indications; in some cases even "forever." In cases in which complete collapse of the lung was attained we may expect a successful termination in one year, and in some acute cases the treatment may be discontinued within one year. Forlanini, Brauer, and others have had in some cases good and even permanent results after six months' treatment. It is, however, better to continue for at least two years in all cases. In chronic cases we must consider two years as the absolutely shortest period of treatment, and in doubtful cases it must be prolonged for three and even four years. The inconvenience to the patient in having infrequent refills, four to six annually, is so trifling considering that he can pursue his vocation, compared with the hazards of a relapse in case the lung is allowed to reexpand too early, that it is better to continue the treatment for a year longer than to stop one month too early. If the disease is extensive it is advisable that the inflations should be continued over long periods of years, perhaps "forever."

This should not deter us from applying this treatment in all cases in which it is indicated. We must always bear in mind that in "hopeless" cases an artificial pneumothorax often saves life, gives comfort and in some even efficiency, which cannot be obtained by any method of treatment practised at present. All our cancer surgery, of which some surgeons speak with justifiable pride, does not give results comparable with artificial pneumothorax in hopeless cases of phthisis. No surgeon hesitates in performing the operation of gastrostomy for cancer of the esophagus or stomach, knowing that in all probability the patient will not survive three months. Palliative enterostomies, tracheotomies, etc., are performed with confidence that the best is done, even when the life is not saved, but comparative comfort is given during the last days of life of the unfortunate patient. In hopless cases of phthisis artificial pneumothorax does much more than this palliative surgery: it removes the symptoms which make the life of the patient miserable —the cough, the expectoration, the fever, the night-sweats, anorexia, hemoptysis, etc.; reinvigorates him, and in many cases renders him efficient at his calling or even to do some light manual labor, immaterial whether he is ultimately cured or not. The only inconvenience it puts him to is that he must report every month or six weeks for a refill, which he knows from personal experience is painless and bearable. In a large proportion of cases artificial pneumothorax is more than palliative—it cures the disease radically and should therefore be applied in all cases in which other methods of treatment have been tried but found wanting.

A SIMPLE, EASILY REGULABLE METHOD OF APPLYING ABDUCTION IN THE TREATMENT OF SHOULDER DISABILITY.

By WALTER M. BRICKNER, M.D., F.A.C.S.,

NEW YORK.

ASSOCIATE SURGEON, MOUNT SINAI HOSPITAL.

THE importance has been learned of early abduction after reducing fractures and dislocations of the head of the humerus. Not sufficiently recognized, however, is the very great value of abduction in the treatment of shoulder disability ("stiff and painful shoulder").

In his classic articles on subacromial bursitis Codman[1,2] described a clumsy apparatus, much copied in text-books, for maintaining abduction after forcibly breaking the bursal adhesions under narcosis. This consisted of a padded iron-wire brace extending from the hip to the axilla and from the axilla to the hand, fastened to the trunk by a spica about the shoulders and a belt about the waist, and, at night, bandaged to the arm. Such an apparatus not only provides no easy means of regulating the abduction from hour to hour, but it is awkward to apply and very awkward to wear. Fastened to any such brace, a person cannot conveniently get about the house, and certainly he will not go outdoors; one might much better, therefore, submit to the equally confining but much less awkward and uncomfortable abduction method described below. Codman himself says[2] that his method of treatment "was a very arduous one for the surgeon, and caused a good deal of complaint from the patients," and that "the splint, in order to be comfortable, required frequent adjustments . . . ." Indeed, he seems to have abandoned both the apparatus and the "brisement forcé" of the bursal adhesions—a procedure much more uncertain and more dangerous than open operation.

In a later publication Codman[2] called attention to the fact that "when a person stands with the knees straight and the finger tips close to the floor, the humerus is abducted on the scapula by gravity alone without muscular effort." To secure the abduction of a "stiff and painful shoulder" Codman recommends the employment of this movement, so familiar in setting-up exercises. He says "this will prove of assistance in *every* shoulder case, and should become of daily use in every large hospital clinic." The procedure is worth trying in all cases, and it will no doubt work well in those in which the limitation of abduction is due to simple weakness or to the mere fear of pain. In my experience, however, when there is real spasm or mechanical obstruction (adhesions or contractures in the periarthric structures) gravity, thus suddenly and briefly applied, will *not* effect abduction of the humerus on the scapula.

The simple abduction method here illustrated I employ very often in the treatment of shoulder disability—both in early cases to prevent, and in late cases to cure, the stiffness and loss of motion; both in disability arising from "sprains and tears of the antero-inferior aspect of the capsule," as described by T. Turner Thomas,[4] and in such cases of subacromial bursitis as do not require operation, and,

especially, when not associated with injury to, and lime deposit in the supraspinatus tendon.* Thus, by its continuous use for two weeks I have cured three successive cases of forward *subluxation of the head of the humerus*, causing extreme shoulder disability.

The patient is put to bed in semi-recumbent position, supported on pillows, not too soft. He abducts the affected arm, on the pillow, as far as he comfortably can. A muslin bandage is then looped lightly about the wrist and carried to a convenient spot on the headpiece of the bed, where it is fastened. The upper end of the bed is then raised on "shock blocks" or chairs. As the patient's body little by little slides down in bed his arm travels (relatively) further and further up, and thus a shoulder that obstinately resists forcible efforts at abduction yields steadily, painlessly, to this gradual countertraction, which the patient often does not even feel. It is striking to observe that a person whose shoulder for months has not been abducted, actively or passively, beyond 45° put thus to bed in the afternoon, may be found the next morning with his arm alongside his head! Few cases respond so quickly, however. The treatment may require a week, or even more, to restore full abduction.

Omitting from consideration, for the moment, the effects of the rest and the continued abduction position itself—both important factors—it will be seen that my procedure is the opposite of the calisthenic movement advised by Codman. Whereas he would apply gravity abruptly and only briefly to the arm itself—which a spastic shoulder will not yield to—I apply it gradually and continuously to the rest of the body—which a spastic shoulder does yield to. It should be said, however, that, finding his brace unsatisfactory, Codman tried "tying the patient's forearm by means of a forearm splint to the head of the bed,"—obviously possible only to maintain, and not to secure abduction.

The procedure here described can be variously modified.

Instead of fastening the bandage sling to the head of the bed it may, in the daytime, be looped over the cross bar (or a pulley) and carried down to the opposite hand, and the patient allowed to amuse himself by pulling upon it from time to time, which will hasten the results in suitable cases.

In those instances in which the condition does not demand, or the patient will not consent to continuous treatment, it may be employed only at night. It may be applied also, but not so satisfactorily, in a large reclining chair.

If continued abduction grows painful or irksome it may be intermitted occasionally, the patient merely slipping his wrist out of the bandage loop and resting the arm on a pillow or by his side. In thus treating subluxation, however (and I recommend it only when the subluxation is best reduced in this position), the abduction should not be intermitted.

A back-rest may be substituted, if for any reason preferable to the exaggerated Fowler's position.

Pillows may be piled up comfortably under the arm as auxiliary to or, from time to time, substitute for the sling.

In many cases of shoulder disability there is limitation of external rotation. In such cases the forearm will not drop back on the pillow in the plane of the body, and it should be supported on a small additional pillow placed behind it. This device is desirable sometimes in other cases merely to relieve the fatigue of continued rotation.

It need hardly be added that if, when the patient slides down as far as the bed will allow, the arm is not fully abducted, he should prop himself up again, and shorten the sling or apply it at the elbow.

All of these adjustments can be made by the patient himself, and no special attendant is needed.

It should be added that this plan of treatment is not advised for recent fractures or dislocations (where moderate, fixed abduction is required), for arthritic conditions, nor for any shoulder disability until as definite a diagnosis as possible is established by all available means. In cases of adhesive subacromial bursitis with calcareous deposit in or on the injured supra- or infraspinatus tendon, open operation, in my experience, will yield much more speedy results. At any rate, in such of these cases as may be submitted to this gradual abduction treatment, if it aggravates the pain or fails to promptly increase the arc of motion, it should be abandoned for a more radical measure.

*This deposit is not in the bursa as it is generally supposed to be.

TUBERCULIN IN PULMONARY TUBERCULOSIS.

By LEROY S. PETERS, M.D.,

ALBUQUERQUE, N. M.

No one method of treatment probably has stronger adherents or more bitter enemies than has tuberculin. Back at the time of its discovery by Robert Koch when the profession went wild with the new cure, then through the period of reaction when but a handfull of scientific men dared cling to its use, down to the present conservative era, tuberculin has been praised and damned.

We have now been using tuberculin therapeutically for nearly a quarter of a century and the evidence for and against would fill volumes, yet who shall sift, so to speak, the tares from the wheat, and judge which deductions rest upon a more scientific footing? Surely the opinion of good clinicians should be heeded, but when one finds names of equal merit at opposite poles we are lost in a maze of uncertainty.

The use of tuberculin therapeautically must needs be more or less empirical. I say empirical since there is little if any scientific proof of its usefulness. No one has yet, except in a very superficial way, far from convincing, been able to immunize animals against tuberculosis by the use of tuberculin. True, one can produce an immunity against the tuberculin, but one cannot produce an immunity against the disease.

However, it is not necessary to await a test-tube experiment or a definite statement from a laboratory worker to convince the average clinician who has followed the use of tuberculin over any considerable period of time of the value of this method of treatment.

To-day I believe we can divide the profession into three classes: (1) Those who are strong opponents of all tuberculin treatment, taking the stand of the great majority in the early nineties when the reaction set in against its use. (2) Those tuberculin optimists who in their zeal go much too far and little realize that in addition to the good they do they may and do produce a great harm by their enthusiasm. (3) The conservative physician who knows from a careful study and long experience the value of tuberculin in the right patient and the harm that may be done in the wrong patient. Certain it is that tuberculin is a two-edged sword, capable of cutting both ways, and woe to the patient and to the physician when both edges do their work.

In choosing a tuberculin I believe there is little if any difference in the various preparations offered. It is an absolute fact needing no demonstration that the therapeutic action of all tuberculins is the same. One may contain a larger percentage of foreign protein obtained from the culture media than another but the curative principle offers no material difference.

As I have already stated no tuberculin possesses a direct curative power, in other words it is no antidote for the disease, as obtains for example in the serum treatment of diphtheria. Sahli says the action depends upon an actively immunizing curative process, or upon the activity of those processes initiated by the toxins of the disease by which the organism can protect itself against infections. Or to put it differently it depends upon arousing the true natural healing processes.

Now granting the Wolff-Eisner theory as a plausible explanation of the action of tuberculin we can apply it to the above statement of Sahli. Wolff-Eisner divides the antibodies of tuberculosis into two kinds: (1) the primary lytic antibodies with which the tuberculin and the tubercle bacilli combine to form toxic decomposition products by means of which we assume that the bacilli are, if not at once destroyed, at least weakened; these decomposition products cause the general and localized irritative actions. (2) The secondary antitoxic antibodies which act against the toxic action of the lysinized tuberculin and tubercle bacilli. The action of the lysinized tuberculin or the first set of antibodies is one of stimulation of the non-specific curative forces of the organism, *i.e.* inflammatory, hyperemic, and exudative, together with leucocytosis and caseation. All these healing forces are to a certain extent present in the natural course of tuberculosis, but they are increased by the injection of tuberculin. The action of the secondary antitoxic antibodies is one of tox-immunity or the establishment of immunity against the toxic action of the tuberculin. In a word the increase of tox-immunity or the specific antitoxic efforts of the organism and the stimulation of the local processes of physiological defense in the tuberculous foci is the essence of tuberculin treatment.

But herein lies the danger of tuberculin when administered with too rapid increase of dose or started in too large doses. Nothing can be gained in the majority of patients by trying to lessen the time of treatment. So-called general reactions should be avoided, since when once produced and the local foci lighted up, no one can foretell the grave consequences that may follow. Here we have an over stimulation and no doubt a greater or less destruction of tissue at the point of infection. The same process is seen in unfavorable or progressive types of clinical tuberculosis. Here nature sets free too large an amount of tuberculin daily into the blood stream. The irritative action of the local process is excessive with a resulting spread of the infection and a breaking down of the tissue elements. In all tuberculin treatment then the aim should be to inject just the optimum dose, or a dose in other words that will produce irritative action with the least possible tissue damage.

It does not necessarily follow that because a few patients respond to large doses with coincident high fever and marked local inflammatory changes with no apparent ill effects, such a course is justifiable. On the contrary, the physician who will in spite of the large amount of evidence against him persist in high dosage does untold harm to the greater part of those who unfortunately come to him for treatment. Studied in the light of common sense there can be no excuse offered for the so-called heroic method of tuberculin administration. All that is necessary (and I wish especially to emphasize this point) is to exert a gradual influence by the injections, arousing into action the two healing processes that are already existant in the natural recovery from tuberculosis, namely the local irritative process and the antitoxic defense.

The question now naturally arises as to why the tuberculosis cannot be as well healed by the natural processes which are essentially the same as by tuberculin administration? This is explained by the fact that some patients lack the ability to react to their own poisons and are therefore unable to produce the necessary factor essential to the healing process. On the other hand, certain types overdo by natural means what we attempt to accomplish by tuberculin. They do naturally what the advocate of high dosage does artificially. Then, too, especially in the early cases, according to Sahli, the toxin production is so gradual that the irritative action causing the formation of the lytic and antitoxic antibodies may easily prove less than that afforded by subcutaneous injection when the tuberculin is at once diffused directly into the general circulation. Then, too, in subcutaneous injections only a small part of the toxin goes to damage the tuberculous foci, the larger part causing the production of antibodies.

Unless the two factors I have mentioned are brought into play, healing of the tuberculosis cannot or does not take place. Clinically this is seen in patients who take tuberculin like water, and yet when a tox-immunity or an immunity to the tuberculin has been established, as is evidenced by a dose of 100 or 1,000 milligrams, they are far from well. Here we have merely established a tox-immunity and the irritative lytic action is lacking as is also the co-action I have mentioned at the sight of injection, viz., inflammation, caseation, leucocytosis, etc.

There is another important side to small dosage which deserves mention. Many patients when repeatedly subjected to high fever and general systemic reactions object to a further course of the tuberculin. But when we begin with a small dose and gradually increase, watching the effects and carefully noting the symptoms, the patient will pass through the entire treatment with barely a disagreeable feature, and the goal aimed at in the beginning will have been reached without interruption or a possible quitting of the treatment.

In the course of the treatment one at times finds a patient who is hypersensitive. A repeated dose

gives a reaction and even a lowered dose causes the same effect. Some of these patients reach a stage where they will not tolerate any dose. This hypersensitiveness is clearly allied, according to Wolff-Eisner, Hamburger, and Roemer, to immunity against tuberculosis. Koch noted that if guinea pigs already tuberculous are given cutaneous injections of living tubercle bacilli the second infection does not develop but produces ulceration, which immediately heals, showing therefore that the first injection has produced local immunity against the second.

There can be no doubt then that this immunity is connected with and is caused by hypersensitiveness. (Sahli.) This is shown by the fact that immediate inflammatory and necrotic changes take place at the site of the second infection, while after the first local changes only begin to develop within fourteen days. These phenomena are all due to lysin, which in these animals is increased by disease. The same holds good in hypersensitive patients. The lysin content of the body far in excess of the usual amount immediately unites with the tuberculin and produces a marked inflammatory reaction. In such a case, if the injections are persisted in a great deal of harm can result; on the other hand such a patient shows a marked immunity against his tuberculosis.

Having outlined now in a very superficial way the working basis for tuberculin treatment, let us consider the kind of tuberculin, the dilutions, and the method of dosage. As I have already stated, the choice of a tuberculin matters little. Let the man use that form with which he is best acquainted and if acquainted with none let him choose one and learn to use that one scientifically.

At present I believe every pharmaceutical house and laboratory puts out a diluted tuberculin for ready use by the general physician, who is too busy to make his own dilutions. Also accompanying this is a set of directions. Armed with these weapons many a beginner sails out upon the sea of tuberculin therapy with his craft guided by the dose book and the bottle wrapper. Sooner or later he finds himself swept upon a rock and naturally tuberculin must needs receive the blame. This same doctor would scoff at a bottle of ordinary medicine which dared to flaunt the dose and the therapeutic indications in his face.

Make your own dilutions. Common sense and a knowledge of the metric system together with a graduated pipette, a bottle of carbolic acid, and sterile water will aid you in the simple task. If you have not time to bother with this end of tuberculin therapy you have not time to bother with the greater and far more important part of treating the patient.

I have been using tuberculin seven years and three years of that time was necessary to convince me that even the moderate dose was far too large for a beginning; 1/10,000 of a milligram was the initial dose for two years of my apprenticeship, then 1/100,000 seemed a safe procedure. Four years ago I had reached 1/1,000,000 and in some cases I begin with 1/10,000,000 of a milligram. Some men have laughed at me for presuming to get a reaction on 9/1,000,000 of a milligram, as I have stated in another paper, but I had the pleasure of showing a marked local reaction with slight systemic symptoms as evidenced by a degree of fever twelve hours after the injection of 6/1,000,000 of a milligram of tuberculin.

The method of dosage is as follows: Beginning with a solution in which one cubic centimeter is equivalent to 1/100,000 of a milligram I inject twice weekly until such a point where a local reaction is manifest. This is a danger signal and I repeat the dose or drop back if the local reaction still continues. Passing this reaction point the injections are increased until another local reaction is noted when the same procedure is repeated. Now, if at any time during the course of treatment I find a dose that seems to agree with the patient as is evidenced by a drop in temperature, lower pulse rate, less cough and expectoration, and a feeling of well being I hold that dose and keep repeating it until the favorable effects disappear when I consider the dose to have outlived its usefulness and a rise is indicated. Sometimes one will find that a dose somewhat lower than this I have just desribed will do even better work, the so-called optimum dose of some authors. The dose is given twice weekly until 1/10,000 or 1/1,000 is reached, when I space them weekly.

The treatment is continued so long as the patient does well or until an arrest of the disease is attained. If at any time hypersensitiveness develops I, of course, discontinue the treatment, otherwise much harm might result. I have no limit to the length of the course or to the number of injections, but am guided solely by the condition of the patient himself.

There are a number of outside factors which call for a temporary suspension of treatment, such as acute coryza, indigestion, menstruation, and various indispositions. After such suspension of the injection, the treatment should be recommenced as if a tuberculin reaction had taken place. In all such cases the dose, of course, should of necessity be lowered.

Tuberculosis, like all other diseases, is more amenable to treatment in the early stages than in the more advanced. Therefore, best results are obtained by tuberculin treatment in the early cases, which is, of course, true of all other therapeutic measures. However, I do not confine my choice of cases to incipients alone. If such were the case I would show but few tuberculin treated patients, whereas my records will show about 50 per cent. so treated.

Roughly speaking, tuberculous invalids may be divided into three classes from the standpoint of tuberculin treatment: (1) The incipient class which, as I have said, offers the best results; (2) The patients who run a maximum temperature of 99° to 100°, in whom excellent results can be obtained by careful tuberculin therapy; (3) The febrile class in which the temperature curve reaches 100° to 103° or over and in which I believe tuberculin to be contraindicated. Later, by routine treatment a number of these patients may be made tuberculin subjects. I doubt very much if tuberculin in small doses can do this class of patients harm, but, on the other hand, I feel that such treatment would be a waste of time as well as of tuberculin.

Let us remember that as yet we have no specific for tuberculosis, and tuberculin nor any other one factor in the treatment of this disease will raise the dead consumptive. Yet I feel that conscientious and careful use makes tuberculin an agent for great good and on the other hand, carelessness and ignorance of its action makes it an agent for untold harm.

DISEASES OF THE SKIN IN PREGNANCY.*

By PAUL E. BECHET, M.D.,

NEW YORK.

ASSISTANT PHYSICIAN, NEW YORK SKIN AND CANCER HOSPITAL; ATTENDING DERMATOLOGIST, ROOSEVELT HOSPITAL DISPENSARY; ASSISTANT DERMATOLOGIST, PRESBYTERIAN HOSPITAL, OUTPATIENT DEPARTMENT.

PREGNANCY is a contributory factor in a number of dermatoses. A close relationship exists between the skin and the changes in the general metabolism incident to the pregnant state. Virchow and Neusser believed in the existence of some relationship between the ovaries and the skin. I have in a recent paper on the etiology and treatment of hypertrichosis analyzed the history of 146 cases of this anomaly. Of the 146 women, 106 were unmarried; in none of the cases did hypertrichosis occur before the establishment of puberty; 80 women, of the 146, had serious menstrual disorder, and 25 per cent. of the remainder had minor anomalies of menstruation. These facts, coupled with evidence presented by others, convince me that hypertrichosis is the result of a functional or organic derangement of the ovaries, whereby some unknown hormone with a specific influence on pilosity is so altered in character that pilosis results. While any of the diseases of the skin may coexist with pregnancy, those most intimately connected with it are: pruritus, chloasma, herpes gestationis, paronychia, alopecia, fibroma molluscum gravidarum, prurigo gestationis, and impetigo herpetiformis. Most of them owe their origin to the toxemias of pregnancy, and, with the exception of herpes gestationis and impetigo herpetiformis, rapidly disappear after the birth of the child. All of these diseases, with the possible exception of impetigo herpetiformis, are found in other than pregnant women.

Impetigo herpetiformis is the most interesting of the diseases associated with pregnancy, because while Dubreuilh, Kaposi, and Whitehouse have observed the disease in three males, it occurs with but very few exceptions in women in the pregnant state; in fact, the existence of pregnancy is considered a factor in its diagnosis. The disease is very rare; up to 1911 there were only 20 reported cases. The American Dermatological Association reported one case among 58,121 miscellaneous diseases of the skin, for the years 1909 and 1910; this is fortunate, for the disease is usually fatal, and very little hope can be held out for the patient. While microorganisms have been found, nothing definite has been established. Its etiology is necessarily obscure, in view of the relatively small number of cases reported. Scheuer believes the disease is of toxemic origin, and that bacteria play only a secondary role in its causation. The most promising treatment for this condition is the injection of small quantities of blood serum, obtained from normal pregnant women, as first suggested by Mayer. It has brought about the recovery of a few of the cases. Veiel reported a severe case of bullous disease in a pregnant woman, which healed entirely after two injections of fresh sterile serum from a healthy pregnant woman. In view of the disappointing results attained by the older methods, this would seem to be of decided value.

General pruritus occurs most frequently in those of neurotic temperament. It is a sensory neurosis and is mostly dependent on the digestive and intestinal derangements which usually occur in the pregnant state.

*Read before the Bronx Medical Association, October 7, 1914.

Genital pruritus may be idiopathic, or be caused by vaginal discharge, parasites (seat worms), or glycosuria. The treatment of general pruritus consists chiefly of the elimination of the causative toxins, through stimulation of the activities of the excretory organs. Locally, the use of a lanolin ointment containing 1 to 2 per cent. phenol and 2 to 5 per cent. menthol often gives relief. The treatment of genital pruritus depends upon its cause. If it is due to the oxyuris vermicularis, rectal enemas of infusion of quassia, or five grains of santonin at night, followed by a saline in the morning, are indicated. If caused by glycosuria the patient should be put at once on an antidiabetic diet. In case a vaginal discharge is responsible, a mild astringent and antiseptic douche should be given daily. Locally, the calamine and zinc, or magnesia and zinc lotions, are very soothing.

Chloasma is a hyperpigmentation of the skin, most frequently located on the face. It is commonly observed during pregnancy, and when it does occur in pregnant women it may be considered as an exaggeration of the physiological tendency to an increase of pigmentation which usually occurs in women in this condition. Kaposi reported the case of a woman in whom increased pigmentation of a large mole on her neck was the earliest sign of pregnancy. Wychgel found that the pigment deposited in the papillary layer of the skin responded to the usual tests for iron. He considers that it is derived from the hemoglobin of the maternal blood cells destroyed in the fight against the fetal tissues.

Herpes gestationis is dermatitis herpetiformis and pregnancy is not an important factor in its production. It appears just as frequently in men, children, and non-pregnant women. It was thought to be connected in some way with pregnancy, because several observers (Milton, Bulkley, White, Duhring) have reported cases of the disease occuring in pregnant women and disappearing after childbirth.

Paronychia, or loosening of the finger nails, is a painful condition, usually dependent upon malnutrition. It usually appears in individuals of neurotic tendency. It may also be caused by the trichophyton; a number of cases of onychia and paronychia are found, if sufficiently investigated, to be due to this fungus. The treatment is a prolonged one, and if the condition is dependent on malnutrition, recovery takes place only after the completion of pregnancy.

Alopecia is a nutritional disturbance and the loss of hair usually takes place during, or shortly after the puerperium. It stops with the improvement of the general health. The loss of hair is never permanent. Locally one may use stimulating lotions, but the most important thing to do is to upbuild the patient, thereby removing the cause of the condition.

Fibroma molluscum gravidarum is extremely rare; it consists of one or more sessile, pedunculated, soft or firm, painless tumors, the size of a pea to that of an egg, which disappear spontaneously, postpartum.

Prurigo gestationis is a name given by Besnier to an itchy eruption, consisting of pin-point to pinhead size papules, closely grouped, and especially locatedl on the extensor surfaces of the hands and feet. It appears usually after the third month and disappears after the birth of the child. It recurs in successive pregnancies.

40 EAST FORTY-FIRST STREET.

MEDICAL INSPECTION OF SCHOOLS IN CONNECTICUT.

By F. H. BARNES, M.D.,
STAMFORD, CT.
SUPT. DR. BARNES' SANITARIUM.

This problem confronts us at the present time as never before and the medical profession is waking up to the fact that much is expected of them in an advisory capacity. Parents of our children are greatly interested in the subject and are seeking the best methods of bringing up their boys and girls along hygienic lines, realizing more and more the value of robust physical health. Some states already have laws making the physical examination of school children compulsory. In others the work is carried on by health departments and school boards and is simply a local affair. The neighboring States of New York and Massachusetts have laws requiring examination for physical defects in the children atending their schools. In Connecticut we have no State law governing this matter. There is a law requiring the examination of the eyes of public school children every three years. This law was passed in 1910 and its provisions are found in Section 251 of the General Statutes of the State. In the report of the State Board of Education for 1913 we find the following: "This investigation calls attention to many defects of eyesight otherwise unobserved and the evidence is conclusive that proper remedies are in many cases applied." It is interesting to note that during the year 1911 (their report for 1914 is not obtainable as yet) the eyes of 154,379 children were tested and among these were found 14,824 cases of defective eyesight or a percentage of 9.6.

During the session of the Connecticut State Legislature 1912-1913 a bill requiring medical inspection of public school children was presented by the Connecticut State Medical Society but unfortunately it failed to receive favorable report from the committee having the matter in charge. During the previous session 1910-1911 three separate bills were presented but failed to receive favorable consideration although the provisions of all three were merged into one bill. The representatives of the smaller towns throughout the State were present in force at the hearing and assailed the proposition bitterly, insisting it was impossible for scattered communities to have such inspection. If the bill had been limited to provide for inspection in towns and cities having a population of 5,000 or over it would probably have become a law. If we are to have a law governing the matter in this State it must be after a campaign of education by the medical fraternity in all its towns and cities. In order to find out what some of our cities are doing in this line letters were mailed to the Superintendent of Schools in ten of the largest cities in this State, New Haven, Bridgeport, Hartford, Waterbury, New Britain, Meriden, Stamford, Norwich, Norwalk, and Danbury. Of these cities the last three, Norwich, Norwalk, and Danbury, have no system of medical inspection. I could get but little data from the replies received and was led to believe that the records of the inspection we now have were not given to the public to any great extent. No doubt good results have been obtained and I will cite a few of the interesting facts to be gleaned from present information. The report of the New Haven Board of Health for the year ending Jan. 1, 1913, shows 11,949 pupils inspected; medical treatment was advised for 4,189. Contagious and parasitic diseases were found to the number of 1,387. Pupils vaccinated 1,562. The school nurses' report shows 4,112 treated for vermin, 7,308 for skin diseases, 929 eye and ear diseases, 3,616 sores and injuries.

The report of Bridgeport Medical Inspector, Dr. F. A. Sherman, shows a list of defects and diseases as follows: Defective vision 528, defective nasal breathing 91, enlarged cervical glands 171, defective hearing 74, chorea 101, cardiac disease 4, orthopedic conditions 58, malnutrition and anemia 221, anemia 1,369, enlarged tonsils and defective nasal breathing 1,959, defective teeth 7,776, defective palate 11, defective mentality 65, pulmonary disease 3, scabies 98, pediculosis 687, impetigo contagiosa 463, and blepharitis 595.

The report of the Board of Health, City of Hartford, year ending December 31, 1913. Excluded from school by medical inspector for following discases: measles 21, diphtheria 30, mumps 19, skin diseases 163, parasitic diseases 833; miscellaneous 111, chickenpox 3, scarlet fever 3; total 1,183.

Waterbury has medical inspection but I was unable to get any data as their Municipal Register has not been published for the year 1913-14.

The New Britain Medical Inspectors' report for the year ending June 1913 shows total number examined 1,075. The following conditions were found: anemic 54, abscess of ear 9, alopecia areata 3, acute tonsillitis 44, bronchitis 3, chickenpox 13, corneal ulcer 4, cystitis 3, conjunctivitis 27, chorea 1, deaf 6, defective vision 106, eczema 43, endocarditis 2, enlarged tonsils 65, enlarged glands 16, fracture of wrist 1, furuncle 7, goiter 1, hives 2, hip joint disease 2, herpes 28, infected leg 3, infected hand 12, indigestion 9, impetigo 15, jaundice 1, laryngitis 2, measles 1, mumps 9, necrosed jaw 1, nervousness 6, rheumatism 1, scabies 8, mentally deficient 4, rhus poisoning 33, pediculosis 26, ringworm 7, sore throat 11, stye 3, tuberculous glands 6. Four children were found desquamating after scarlet fever. One case of diphtheria was found attending school regularly. Frequent visits were made with the school nurse to the various schools and all children below the seventh grade were seen at least once.

The Medical Inspector of Meriden reports for the year 1911-12 number of physical examinations 3,464. Among these 1,413 showed some defect, 848 were found to have defective teeth only. For the year 1913-14 there was a total of 3,496 examinations. Of these, 1,467 were found defective, 716 had defective teeth only. Among the defects found were 144 cases of measles, 2 of diphtheria, chickenpox 9, pertussis 35, pediculosis 898, ringworm 16, scabies 10, impetigo 67, favus 3, trachoma 1, and conjunctivitis 22.

Stamford Medical Inspectors report physical examinations to the number of 2,057. Of these 702 had enlarged tonsils, 471 nasal obstruction, 45 defective hearing, 20 discharging ear, 175 poor nutrition, 742 defective teeth, 76 stooping shoulders, 5 lateral curvature, 75 showed nervous conditions, including chorea and epilepsy, and 3 hip joint disease. Several backward children were found with some degree of mental enfeeblement.

The value of medical inspection has already been shown in this State. It is, however, just commencing to fill the important place it should in our public schools. One cause for failures in the past has been that the right men were not selected for the work. It requires time and study, also original ideas on the part of the physician in charge. He must have patience and tact, at the same time be willing to re-

ceive suggestions of a helpful nature. In many instances the inspection has been done in a haphazard manner, little attention being paid to systematic investigation of what other cities and towns were doing in the same line. Medical inspectors should visit other towns and note their methods. Many new ideas can be obtained in this manner and later worked out in the schools under their supervision. A careful physical examination of every child of school age must be made. This information should be carried on a card system properly indexed for future reference. If physicians having the work in hand use good judgment they will be able to placate hostile public opinion and easily get the cooperation of parents generally. Medical inspectors should not only do their routine work but should at the same time educate the public to see the necessity of systematized effort for the welfare of their children. At least once or twice a month through the school year lectures should be given the parents in the assembly hall of one of the various school buildings. They can be given in connection with some little entertainment by the children. Our foreign population are willing and anxious to learn what is best for their progeny and no better method can be obtained to awake their interest and make them enthusiastic for the work. The school nurse should follow up the work of the physicians both at school and in the home to see that the children secure proper treatment. Under no condition, however, should the entire work of inspection be left to the nurse alone, as has been suggested by some school boards. The reason for such procedure probably being due to the lack of results shown by the medical inspector in those particular towns. Medical inspectors should examine every child once a year if possible. They should watch carefully for signs of contagious disease among the children. Many backward and feebleminded children are found in our schools. These should be properly classified and sent to separate classes or to our State Institution for the feebleminded. Connecticut is greatly in need of enlarged facilities for this group. The buildings at Lakeville are filled to capacity and yet no provision has been made for the large number who should be receiving State care at the present time. Suggestions should be given for the improvement of home conditions surrounding the child, both as to cleanliness and proper care by the parents. In fact a watchful eye should be kept to see that everything possible is done to protect the life and health of the many children entrusted to their care.

Connecticut should have a State law at the coming session of the Legislature to make medical inspection compulsory in all her towns and cities.

A SUGGESTION IN CASES OF LATE OPERATION FOR INTESTINAL OBSTRUCTION*

By JAMES C. JOHNSTON, M. D.,

M'ALESTER, OKLAHOMA

In late cases of obstruction there is an added hazard of toxemia; and this often develops after several hours of what is apparently a perfect reaction from both the obstruction and the operation. Permit me to suggest a plan which may prove of value in preventing the toxemia.

Given a case presenting the following symptoms: Recurrent and colicky pain in the abdomen. Nausea. Vomiting of first mucus, then bile and later foul smelling material, suggesting feces; increasing in amount and often amounting to a projectile type of vomiting. Borborygmus of variable degree. Areas of flatness on percussion over abdomen where normally it should be resonant. Leucocytosis of moderate degree. Normal temperature, or a history of no fever at onset.

Now, when we operate in such a case and remove the obstruction, we have met the mechanical indication; but we have not prepared that part of the intestine lying below the obstruction to withstand the resorption of fermented materials from the upper segment of the intestine.

The pathology of this dilated portion permits certain changes in the wall itself, through which even bacteria may pass, or perhaps merely allows a large quantity of fluid to accumulate in the intestine above the obstruction; this fluid is usually a mixture of hypersecretion, inflammatory exudate, and blood. This is followed by fermentation and venous stasis, and the destruction of the epithelium; then follow necrosis, ulcer, perforation, peritonitis and more often death, if operation has been long delayed. The operation often performed is a simple enterotomy to liberate the contents of the intestine at the point of greatest distention; the wound being thus closed with a dependable intestinal suture.

Let me suggest that, instead of closing the intestinal wound at once, the operator clamp the lower segment of intestine and thoroughly irrigate the upper segment for as great a distance above the obstruction as may be easily reached, using sterile water, or half strength of the customary physiological salt solution. It is important that none of the accumulated material above shall enter the empty and thirsty intestine lying below the obstruction.

When the operator is thoroughly satisfied that he has met the mechanical requirements of the obstruction, by liberating an incarcerated bowel in hernia, or remedied the condition brought about by volvulus, intussusception, diverticulum, neoplasm, foreign body, or fecal impaction, he should clamp the end of the upper segment and then remove the clamp on the lower segment. Then the half strength salt solution should be slowly instilled into the lower segment with a view to saturating it, so that the rapid absorption of harmful products will be doubly guarded against and diluted when then fecal stream is allowed to resume its course.

If the case presents evidence of not being suitable for complete operation, at once, the intestine may be fastened to the abdominal wall, and the irrigations above and below the opening continued at intervals until the condition of the upper segment warrants the closure of the wound.

If the instillation of the fluid into the lower segment be continued until the upper segment is in a condition approaching normal, I believe we may escape some of the cases of toxemia when the fecal current is restored. This treatment could follow a resection; and even anastomosis done later is much better for the patient and surgeon than an explanation on the death certificate of how it happened.

*Read before The American Association of Railway Surgeons, Chicago, Oct. 14-16, 1914.

Wounds Produced by French Projectiles.—M. E. Delorme records his observations made during a period of five days among 700 wounded German prisoners at the citadel of Blaye. He notes the extreme rarity of wounds of the abdomen, pelvis, and vertebral column, and the relative rarity of wounds of the chest and cranium. He notes, on the other hand, the frequency of serious fractures of the thigh.—*Presse Médicale.*

ETIOLOGY OF PELLAGRA.

By B. W. PAGE, M.D.,

LUMBERTON, N. C.

It is very rare that one finds a typical case of pellagra. It is a disease of many symptoms and of many variations. It may be placed in the sphere of dermatology, neurology, or gastrology, but still it is a general disease. It spreads and is not considered contagious, but infectious it must be. It has the latitude of amebic dysentery and hookworm disease and yet the treatments for these diseases have little effect. Is the microscope of value in the diagnosis of the disease?

For two and a half years I have been more or less interested in the study of intestinal bacteria as a cause of pellagra, but the intestinal microscopic flora and fauna include so many species I have looked with doubt on the pathogenicity of any of them until it is definitely proven. In addition to the colon group of bacteria which are found in feces of pellagrins, I have, for many months, noticed with much interest a bacillus which may be the cause of pellagra.

This bacillus is much longer and more sharpened at the ends than those of the colon group. It is motile, aerobic, sporogenous, stains readily, and grows on culture media. When spore formation is about to occur in the bacillus a point of cloudiness or an area of bright refraction appears in the protoplasm and the cell generally elongates. The spore enlarges, the cell membrane bursts, and the young bacillus emerges through the opening. At first the bacillus is very active and takes the form of a spirillum for a few seconds. It then elongates and becomes less and less motile. Later it may appear rod-shaped, slightly curved, or as a long undulating thread, and suggests the appearance of a streptococcus.

Animal inoculation experiments have not been very successful. Mild intestinal affection was produced in a cat and the bacillus was again observed on microscopic examination. In a man pellagra has been induced by transference of cultures of the bacilli. Pharyngitis and bronchitis developed within three days and were soon followed by definite intestinal and nervous symptoms of pellagra. The microscope revealed the organism in its many forms.

Of the fifty-three cases of pellagra examined, the bacilli were seen in great numbers. Seventeen of these have been examined many times and the organism was present in every instance for many months. The organism has not been seen on examination of healthy individuals and those suffering from other diseases.

The bacillus in culture has been tested by many drugs. A one per cent. solution of ichthyol seemed to have a most decided effect. I have partially tested this drug on fifteen cases of pellagra within the last six weeks. One or two five-grain pills three times a day for eight or ten days apparently cures the average case. In two instances I have known eighty grains of the drug to relieve all digestive and nervous symptoms. The more advanced cases require longer treatment. In so short a time it is impossible to have tested the drug thoroughly, but it seems to act as a specific. With the symptoms, the bacilli disappear.

The organism in all stages of the disease is present in enormous numbers in the contents of the large intestine. I believe it is usually confined to this situation. Its deleterious effects upon the body appear to be largely due to the production of toxic substances, which, in addition to serious intestinal irritation or lesion, may on absorption incite those systemic disturbances which characterize the toxemia. The disease must be spread by direct contact with the excrement of those afflicted with the malady or by flies conveying the parasite to articles of food.

Medicolegal Notes.

Physician's Liability for Negligence of Hospital Nurse.—Action was brought against the plaintiff's family physician, by whose advice she went to a public hospital for a surgical operation. After the operation she was burned by a hot-water bottle that had been left by a hospital nurse in the bed in which she was placed. It appeared from the testimony that the defendant was a member of the associated staff of the hospital and had the privilege of sending patients there for treatment either by himself or by the regular hospital physicians and surgeons; that he agreed for a stipulated sum to perform the operation, but the hospital expenses were to be paid by the plaintiff, to whom he gave a letter of introduction that secured her admission to a private room in the hospital; that she was prepared for the operation by hospital nurses under the direction of the directress of nurses, and etherized by a physician employed by the hospital for that purpose; that she was operated upon by the chief hospital surgeon, assisted by the defendant, and was removed from the operating room to the recovery room by hospital nurses and the physician who had etherized her; that a bed in the recovery room had been prepared for her reception by warming it with three hot-water bottles, one of which had not been removed therefrom, and was hidden from view by blankets which covered it; that the defendant followed the nurses and the etherizer into the recovery room and stood near the foot of the bed when the plaintiff was placed in it; that in the operating room the nurses were in charge of the surgeons, but in the recovery room they were under the direct, immediate, and exclusive control and management of the directress; that the duty of preparing the beds in the recovery room and placing the patient therein rested entirely with the directress and the hospital nurses under her charge, and that the surgeons had nothing to do with it, and that this was the general rule in hospitals. It was held that the injury was caused by the negligence of a hospital nurse, for whose service the plaintiff paid the hospital, and whose work the defendant would not have been permitted to supervise and for whose negligence he was not responsible.—Stewart vs. Manasses, Pennsylvania Supreme Court, 90 Atl. 574.

Practicing Without a License—Evidence—Healing Through Prayer.—In an action to recover a penalty for practicing without a license, the facts showed that the defendant had distributed from house to house a circular in which he claimed to have power to heal through prayer, and that investigators submitting to treatment as patients were charged a fee. The evidence was held to sustain a finding of guilty. The printed circular distributed by the defendants was held to be competent evidence. Such an action, it was held, may be based on evidence procured by investigators who applied for treatment to determine whether the defendant would commit the offense, the investigators not advising or encouraging the defendant to commit the acts constituting such offense. Such an action is not a criminal proceeding in which the venue of the offense must be proved. Although article II, § 3 of the Illionis Constitution of 1870 gives to a person a legal right to pray for the cure of sickness and disease, it does not give him the right to practice medicine without a license.—People v. McTier, 184 Ill. App. 635.

Practicing Without a License—Nature of Proceeding for Statutory Venalty.—The Illinois Appellate Court holds that a proceeding under the Act of 1899, relating to the practice of medicine within the state, to recover a penalty for the offense of practicing medicine without a license, is not a criminal proceeding requiring the offense to be proved beyond a reasonable doubt, and that the burden is upon the defendant to prove that he had such a license.—People v. Klimek, 184 Ill. App. 59.

New York, January 2, 1915.

THE ABSORPTION OF THE CEREBROSPINAL FLUID.

A SHORT while ago (MEDICAL RECORD, Nov. 28, 1914) we took the opportunity to refer to the work of Cushing, Weed, and Wegefarth in which they investigated the question of the absorption and secretion of the cerebrospinal fluid. Since that time there has appeared another article (*Am. Jour. Dis. of Children*, 1914, viii) which presents the results of work directed along the same lines but followed after a somewhat different fashion. The authors, Dandy and Blackfan, have already written on this subject and the present article is an elaboration and extension of their previous one.

They all agree that the principal source of the cerebrospinal fluid is to be found in the choroid plexus of the lateral ventricles and that it is a true secretion. They have been able to produce internal hydrocephalus in animals by plugging the aqueduct of Sylvius even though the greater portion of the plexus had been removed. In one case also they produced hydrocephalus by ligation, low down, of the vena Galeni magna. Dandy and Blackfan differ from Weed chiefly in their theories as to the method of absorption of the spinal fluid. They found that phenolsulphonephthalein appeared in the urine in six minutes after its injection into an isolated section of the spinal cord, a period but slightly longer than that required when the injection was made into the cisterna magna. When a thin emulsion of lampblack was substituted for a small quantity of spinal fluid, they found after one or two hours that the carbon particles were scattered evenly over the entire surface of the brain and cord, thus giving no evidence of the presence of any current in the fluid, such as might be present if absorption took place in any one locality. They rule out the Pacchionian granulations on the ground that they are absent in infants and in some animals. As a result of these observations, they have come to the conclusion that the absorption of the cerebrospinal fluid takes place directly into the blood from the entire subarachnoid space and that it "is a diffuse process and does not take place through specialized structures such as the Pacchionian granulations or through stomata opening into the venous sinuses." These conclusions are contrary to those arrived at by Weed. The latter's method of the injection *intra vitam* of a true solution at low pressure over a long period of time, and the precipitation of this solution *in situ*, enabled him to demonstrate the passage of his injection through specialized structures, the arachnoidal villi. Dandy and Blackfan present two observations which support their theory, viz., the distribution of the carbon particles above referred to and the fact that hydrocephalus may follow the removal of a meningocele. They explain the latter on the ground that the absorption area is so diminished by the operation that the fluid collects. It must be admitted that Weed's theory has no explanation to offer for these facts but it is doubtful if these two observations have sufficient weight to overcome the hypothesis. Dandy and Blackfan discredit the existence of a secondary pathway of absorption along the nerves to the lymphatics since phenolsulphonephthalein injected into the ventricle did not appear in the thoracic duct.

They describe internal hydrocephalus as occurring in two forms: (1) The obstructive type where the hydrocephalus is the result of partial or complete occlusion of the aqueduct of Sylvius, and (2) the communicating type in which no such obstruction exists. In the study of a series of cases they were able to differentiate these types by injecting phenolsulphonephthalein into the ventricle and determining how long a period elapsed before the appearance of the drug in the fluid withdrawn from the spinal canal in the lumbar region. In the communicating type this period was only one to seven minutes, while in the obstructive type it appeared very late if at all. This observation is of therapeutic importance since in the communicating type there is hope of influencing the condition favorably by repeated lumbar punctures while no such hope can be offered in the obstructive form. Where there is obstruction of the aqueduct of Sylvius any puncture for the removal of fluid must be done, of course, into the ventricle. Dandy and Blackfan used their method in the study of eleven cases in which they found seven of type one and four of type two. The causation of the second type is quite obscure. Some of these patients give a history of meningitis and the authors think that secondary to this inflammation there may be some limitation of the subarachnoid space. They also advise against the removal of a meningocele if the absorption from the subarachnoid space as determined by the use of phenolsulphonepthalein, is below normal.

ASEPSIS AND ANTISEPSIS IN WAR.

THE present war will teach us many things from the surgical point of view. It has already impressed upon the minds of surgeons with great force the need of treating wounds as quickly as possible. Especially have the events of the past few months in Belgium and France made evident the necessity for the employment of some means whereby a wound may be rendered aseptic at once. But what the means shall be is a question around which a somewhat heated controversy is being carried on by several of the best known British surgeons, a controversy which seems to hinge on the point as to whether aseptic measures are powerful enough in

the circumstances, or whether antiseptic measures must be brought into play.

Sir Rickman Godlee brought out recently a pamphlet in which he recommended that recent wounds should be swabbed out by pure liquid carbolic acid. Shortly after the publication of this pamphlet, Sir W. Watson Cheyne opened a discussion on the treatment of wounds in war by reading a remarkably able paper, in which he, too, advised the employment of liquefied carbolic acid in the treatment of recent wounds. He stated that one-in-twenty carbolic lotion will not disinfect the cavity of a wound which contains the spores of pathogenic bacilli, while, on the other hand, liquefied pure carbolic acid will kill spores in a very few minutes. Further, he pointed out that carbolic acid is an anesthetic and its application causes very slight pain which subsides almost immediately. Sir Victor Horsley, who always appears to have the faculty of injecting a certain amount of acrimony into all discussions in which he takes part, fiercely combated these views, and went so far as to declare that Godlee's pamphlet should be immediately recalled. He said that he did not believe in escharotic surgery and declared that it was absolutely contrary to the principles and teaching of Lister to use pure liquid carbolic acid in any circumstances in the treatment of wounds.

The discussion has waged now for two or three weeks in the correspondence column of the *British Medical Journal* and is still going on. Some of the letters contributed are illuminating, while all are interesting. A large number of the writers, possibly the majority, uphold the views of Cheyne and Godlee and others suggest other disinfecting agents. The use of petrol is lauded by a few, but also condemned by a few. The employment of alcohol is advised, and it may be recalled that Bevan in the August number of *Surgery, Gynecology, and Obstetrics* in discussing the treatment of gravely infected wounds seen by him in the last Balkan campaign, concluded that the best dressing for badly infected wounds was a wet compress of 60 per cent. spirit.

Again there are those who swear by iodine for this purpose, and it has been stated authoritatively that bullet wounds painted with tincture of iodine immediately after their reception and before the application of the first dressing may be expected to follow an aseptic course. Cheyne objects to the use of iodine on the battlefield, and while admitting that the antiseptic power of iodine is practically the same as that of carbolic acid, he points out the great difficulties in the way of applying it properly under the conditions which prevail in war. Further, iodine causes great pain which lasts for a considerable time. As for the mercurial salts he excludes them altogether, because, although they kill microbes quite readily and in very considerable dilutions, if these organisms are free or in a slightly albuminous fluid, they are of no use when the organisms are present in albuminous or oily substances. Peroxide of hydrogen is valuable as a germicide, but is useless against spores.

The consensus of opinion of those who took part in the discussion before the Medical Society of London as well as of those who wrote to the *British Medical Journal* was that in order properly to disinfect a wound incurred in fighting under such conditions as exist in France and Belgium strong antiseptic measures must be employed. And most of those who argued the point pinned their faith to pure liquid carbolic acid. It should be borne in mind that the skin of the soldiers, who frequently are fighting for days and nights together without changing their clothes, is of necessity dirty and septic. From the skin the microbes enter the wound and infect it deeply in a short time. Also the soil will infect it, and this has been shown in France by the large number of cases of tetanus which have occurred. Therefore, it would seem that a strong antiseptic is called for, one which will not only kill germs but spores. Aseptic measures act splendidly when carried out under favorable conditions, as in a modern hospital. The treatment then is ideal, but circumstances alter cases, and it will not be too much to say that on the battlefield to attempt to rely upon such a procedure will be to lean on a broken reed. Professor Tuffier of Paris, in his report of the inspection of the French Army, read before the Academie on October 13, stated that, in his opinion, antisepsis was incontestably superior to asepsis. Many of the older followers of Lister are now loudly exclaiming that antisepsis has come into its own again. However, the truth of the matter probably is that there are occasions when antiseptic treatment of wounds is indicated, and the time of war is the chief one of these occasions.

ANNUAL REPORT OF THE SURGEON-GENERAL OF THE NAVY.

THE annual report of the Surgeon-General of the U. S. Navy, recently issued, provides very pleasant reading. During the year 1913 the health of the Navy was good, showing a satisfactory improvement over the preceding year. With regard to diseases of special interest, the incidence of malaria increased from 11.63 per 1,000 in 1912 to 12.07 in 1913. This increase was accounted for by the cases occurring on ships in Mexican waters. The value of efforts to protect seamen from the bites of mosquitos was clearly demonstrated. Admissions for diphtheria increased from 0.93 per 1,000 in 1912 to 1.10 in 1913. An outbreak of smallpox occurred on the *Ohio*, and the result of this outbreak appeared to show plainly that in order to avoid contracting this disease vaccination is essential. The *Ohio* and *Vermont* visited Marseille, where smallpox of a virulent type was present. Liberty was granted the men of both ships. On the *Vermont*, whose crew had been carefully examined and vaccinated before leaving home waters, no case of smallpox occurred, while on the *Ohio*, whose men had not been vaccinated for two years, there were twenty-five cases of the disease. Further, eleven cases were malignant and hemorrhagic and in none of these could any scar of successful vaccination be found, but all the fourteen remaining cases of the varioloid type showed vaccination marks.

It is gratifying to note that typhoid fever con-

tinues to show a very marked decrease in the navy. The report, however, points out that this decrease is not altogether satisfactory, seeing that by means of the same procedure, antityphoid inoculation, the malady has been practically eradicated from the army. The question as to how long immunity conferred by this treatment lasts has not yet been successfully answered, and until this has been done the greatest care must be taken to ensure the safety of the men. The incidence of tuberculosis was about the same as for the previous year and venereal infection exhibits a considerable decrease. Alcoholism in the navy has diminished, but there was a slight increase in the rate for mental diseases over the previous year.

Referring to sanitary conditions afloat, the report, among other things, calls atention to the need for hospital ships and emphasizes the point that the only way to have hospital ships in an emergency is to provide them in advance. The personnel of the Navy Medical Department is adequate to meet all demands in time of peace.

THE HEALTH AND PHYSIQUE OF THE CHINAMAN.

It is interesting as well as instructive to learn all that is possible concerning the characteristics, mental and physical, of all races. At the present time when the yellow races are looming large in the public eye, it is especially instructive to gather as many facts as can be gathered regarding the Chinese. Consequently the eighth annual report of the collegiate and medical departments of the Yale mission in Changsha, China, contains many items of value to medical readers.

Referring to the physical characteristics of the Chinese students of the school in question, the report says: The general physical condition of 25 per cent. of 112 such students examined was poor while that of 53 per cent. was only fair, leaving but 22 per cent. in actually good all around condition. In muscular development the percentages were: poor, 39 per cent.; fair, 41 per cent.; good, 20 per cent.; and in the strength tests the average was 306.5 below the average for students of corresponding heights at Yale in America. Nutrition and fatty tissue were subnormal in 27 per cent., and only fair in 46 per cent. Examinations for digestion showed 33 per cent. poor, 25 per cent. fair. In 74 per cent. examination of the feces showed the presence of Ascaris eggs. Total neglect or very ineffective care of the teeth was common, as shown by a percentage of 63 per cent. that needed cleaning.

Unhealthy conditions in the respiratory system were noticeably prevalent, no less than 60 per cent. being in need of treatment for either nose, throat, or lungs. High pitched resonance was evident in 30 per cent. of the lungs examined. Other common defects were: adenoids, 11 per cent.; diseased tonsils, 47 per cent.; polyps, or narrowed fauces, 18 per cent.; deflected septum, 33 per cent.; swollen turbinates, 35 per cent. The vision of 40 per cent. was defective, several marked cases of trachoma were found and there was evidence of it in 16 per cent. In the circulatory system a thickening of the vessel wall was noticeable in 49 per cent., which is abnormal for an average age of 18 years, 6 months. Thirteen per cent. had some enlargement of the heart, while 20 per cent. had either murmurs or other signs of irritability.

From the physical standpoint it is obvious that the Chinese youth, in the district in which the Yale Mission works, is not the equal of his white brother in America. However, this is not a matter for surprise, by heredity he is not so well born in a physical sense, by environment he is not on the same plane, and lastly his mode of living and especially his diet do not tend to render him a large or muscular man.

The Homograde Thermometer.

A clinical thermometer has been introduced recently which the inventor claims to be superior in many respects to the Fahrenheit and Centigrade. This thermometer is the invention of Dr. F. E. Aspinwall of La Grange, Ky., and is described in a paper contributed by him to the *Dietetic and Hygienic Gazette* for September, 1914. According to Aspinwall, in the "homograde," the name by which this thermometer is known, the normal human animal heat at or near the surface of the body, where sensation mostly exists, is the unit of value and every degree in the scale is equivalent to the hundredth part of that unit. Thus every degree and every figure in the scale has an instantly apparent and definite value, and all temperatures are at once understood by comparison with the accepted normal animal heat. The homograde scale may be briefly described as follows: Beginning with 0° at the freezing point, 270° is placed at the boiling point of water. This brings 100° at the accepted normal for blood heat, viz., 98.6° F., or more exactly 98 2/3° F. Dr. Aspinwall has devised a short degree thermometer scale which may have many advantages over the Fahrenheit and the Centigrade, but we fear he will have a vast amount of conservatism to overcome before he can secure its general adoption by the medical profession.

News of the Week.

For the Relief of Belgian Physicians.—The Committee of American Physicians for the Aid of the Belgian Profession held a meeting in New York on December 20, at which time, as previously announced, officers were elected and an executive committee appointed. Inquiries are being made to learn direct from Belgium and Holland the most urgent needs of the profession at this time. The Commission for Relief in Belgium will deliver supplies so far as war conditions will permit, and without cost to the physicians' relief committee. In order to facilitate delivery it has been arranged that all shipments by the Committee of American Physicians will be made in boxes painted with a yellow band. This is in conformity with the color scheme adopted by the Commission for Relief in Belgium, which is designed to facilitate the safe passage of articles across the seas, through the various countries they must traverse, and to their ultimate destination. All subscriptions to the fund for the aid of Belgian physicians should be in the form of checks or postal orders payable to Dr. Frank F. Simpson, treasurer. They may be sent to Dr. Frank F. Simpson, 7048 Jenkins Arcade Building, Pitts-

burgh, Pa. As many signatures are illegible all checks should be accompanied by a card giving the donor's name and address in typewriting or printing. The Union Trust Company of Pittsburgh has been selected as the depository of the committee. Checks will be promptly deposited and will at once be available for the purchase of supplies by the Executive Committee. A weekly report of receipts and expenditures will be made by the treasurer to the members of the committee and through the medium of the medical journals to the medical profession as well. During the week ending December 26 contributions to the amount of $405 were received.

Suggested Changes in the Work of the New York State Board of Medical Examiners.—On December 16 the Regents' Advisory Council in Medicine met and conferred with representatives of the State Medical Society, State Homeopathic Medical Society, State Eclectic Society, and State Osteopathic Society. At this meeting Dr. Heffron, dean of the Syracuse College of Medicine, recommended that pathology and bacteriology should be made separate subjects in the State Board examination; and, likewise, that the question papers for hygiene should be separate from those for sanitation. He also suggested that internal medicine and pediatrics be added to the list of subjects. Both Dr. Heffron and Dr. Williams of the Buffalo School of Medicine urged that the law be amended so as to permit the State Board of Medical Examiners to supplement the present written examinations with practical examinations.

The present requirement of one year's work each in physics, chemistry, and biology for a medical student certificate was severely criticised as being too rigid by President Lowell of Harvard University, who had been invited to be present. The council recommended that this requirement be amended so as to permit students with baccalaureate degrees to matriculate with a condition in physics or biology, or both of these subjects, but not in chemistry.

The several State societies urged the Regents to assume the responsibility of enforcing the Medical Practice Act. Commissioner Biggs of the Health Department said his department would undertake the enforcement if means were provided. The bill introduced at the last legislature defining unprofessional conduct was discussed and amended into a form that was recommended to the Regents to introduce anew at the coming legislature. The definition includes fee splitting and fraudulent advertising.

Canadian Medical Men at the Front.—In addition to the surgeons regularly attached to the Canadian troops now in France and Belgium about one hundred doctors and nurses from the Dominion are engaged in hospital work in France. Twenty members of the teaching staff in the medical department of McGill University, Montreal, with the Dean of the medical faculty, Dr. H. S. Birkett at the head, have effected a hospital organization and offered the same to the British Government. The offer has been accepted and as soon as mobilization can be effected the hospital personnel will sail.

Arrest of Drug Sellers.—Complaints received recently by the police from the parents of many school children that cocaine sellers have been plying their trade outside public schools and that children had come home under the influence of the drug led to the arrest of six men charged with selling the drug. The arrest of three other men about the same time led to the discovery of a large store of cocaine, heroin, morphine, veronal, and other narcotic drugs, to the value of over $10,000.

Epidemic of Diphtheria.—The nine public schools in Hoboken and the public library were closed early last week because of the rapid spread of diphtheria, and 9,000 students, including those in the high school, were started on their Christmas holidays two days ahead of time. One hundred cases were reported in six days.

The Classification of Medical Schools.—Dr. Henry S. Pritchett, president of the Carnegie Foundation for the Advancement of Teaching, will address the coming meeting of the Federation of State Medical Boards of the United States and the Association of American Medical Colleges on "The Classification of Medical Schools." This meeting will be held Wednesday morning, February 17, in the Congress Hotel, Chicago. Dr. Pritchett is understood not to favor the American Medical Association's method of classification.

A Ban on Roller Towels, Common Brushes, Etc.—Regulations recently adopted by the State Health Department, violation of which will be a misdemeanor, forbid the use of roller towels, the barber cup with soap for all comers in the bottom, the unsterilized hair brush in public places, spitting on the street and in public buildings, and various other indecent and unsanitary acts. The regulation will go into effect on March 15 and will rule in all parts of the State north of Bronx County.

State Civil Service Examinations.—The New York State Civil Service Commission announces an examination on January 23 for bacteriologist and assistant bacteriologist in the State Department of Health. Two lists will be established as a result of this examination: one eligible to appointment as either bacteriologist or assistant bacteriologist at a salary of $2,000, open only to men who have the degree of Doctor of Medicine; the other eligible to appointment as assistant bacteriologist only at salaries ranging from $1,200 to $1,500, open to both men and women. Applicants should have a thorough knowledge of the principles of bacteriology and must have had considerable practical experience in the bacterial diagnosis of infectious disease, and a general knowledge of clinical microscopy and of gross and histological pathology is desirable. Candidates will be rated on a written examination relating to the duties of the position and on their general and special training and particularly their practical experience and personal qualifications as shown by their sworn statements, and by answers to such inquiries as the Commission may make of their former employers and others acquainted with their qualifications and experience.

On the same date an examination will be held for the position of physiological chemist, State Department of Health. Salary $1,800 to $2,500. Applicants should have a thorough knowledge of the principles of organic and physiological chemistry. They must have had at least three years' practical experience in physiological or biological chemistry. Candidates will be rated on a written examination relating to the duties of the position, and on their general and special training and particularly their practical experience and personal qualifications as shown by their sworn statements and by answers to such inquiries as the Commission may make of their former employers and others acquainted with their qualifications and experience. Open to men and women, non-residents and non-citizens, subject to

the usual rule giving preference in certification to citizens and residents of New York State. Application blanks for either examination may be obtained from the New York State Civil Service Commission in Albany.

Persistent Milk Adulterators.—A firm of milk dealers in Brooklyn was recently fined $500 in the Court of Special Sessions for three violations of the section relating to the sale of adulterated milk. The members of this firm had previously been convicted twenty-one times for selling adulterated milk, sixteen times for violation of Section 183—returning uncleaned containers to the country, and eleven times for violation of Section 56a—mislabeling of milk.

Medical Society Elections.—The Montgomery County, Tenn., Medical Society, at its annual meeting in Clarksville on December 5, elected the following officers: *President,* Dr. W. R. Newton; *Secretary and Treasurer,* Dr. R. B. Taylor.

The Androscoggin County, Me., Medical Association, meeting at Lewiston on December 8, elected the following officers: *President,* Dr. J. W. Scannell; *Vice-President,* Dr. William Ness; *Secretary-Treasurer,* Dr. Elson B. Buker; *Board of Censors,* Drs. W. L. Haskell, S. E. Sawyer, and J. A. Dupras; *Delegate to the Maine Medical Association,* Dr. J. A. Donovan.

The Athens, Ga., Medical Society elected the following officers on December 5: *President,* Dr. S. S. Sisk; *Vice-President,* Dr. J. C. McKinney; *Secretary and Treasurer,* Dr. H. I. Reynolds; *Censor,* Dr. S. S. Smith; *Delegate to the State Association,* Dr. J. C. McKinney; *Alternate,* Dr. R. P. Glenn.

The Tuscaloosa County, Ala., Medical Association elected the following officers at its annual meeting on November 30: *President,* Dr. J. E. Shirley; *Vice-President,* Dr. H. B. Searcy; *Secretary,* Dr. J. H. Somerville.

The Miriam County, Texas, Medical Association meeting at Cameron on December 9 elected the following officers: *President,* Dr. E. E. Bert; *Vice-President,* Dr. W. R. Newton; *Secretary and Treasurer,* Dr. R. B. Taylor.

The Dallas County, Texas, Medical Society at its meeting on December 9 elected the following officers: *President,* Dr. W. C. Swain; *Vice-President,* Dr. J. D. Watson; *Secretary,* Dr. R. S. Loving; *Board of Censors,* Drs. W. T. Baker and C R. Hannah; *Delegate to the State Society,* Dr. W. A. Boyce; *Alternate,* Dr. A. B. Small.

The Bell County, Texas, Medical Association at its meeting at Temple on December 4 elected the following officers: *President,* Dr. J. J. Terrill; *Vice-President,* Dr. E. D. Maloy; *Secretary and Treasurer,* Dr. L. R. Talley.

The Jefferson County, Texas, Medical Society elected the following officers at its meeting at Beaumont on December 7: *President,* Dr. E. C. Ferguson; *Vice-President,* Dr. W. E. Tatum; *Secretary,* Dr. B. P. Holland; *Censor,* Dr. E. C. Moody; *Delegate to the State Society,* Dr. D. S. Weir; *Alternate,* Dr. O. S. Hodges.

The Tarrant County, Texas, Medical Society elected the following officers at a meeting held at Fort Worth on December 4: *President,* Dr. J. A. Gracey; *Vice-President,* Dr. C. O. Harper; *Secretary,* Dr. James J. Richardson; *Treasurer,* Dr. W. R. Thompson.

The Butte County, Cal., Medical Association at a meeting held at Chico on December 8 elected the following officers: *President,* Dr. M. P. Stansbury; *Vice-President,* Dr. C. C. Landis; *Secretary and Treasurer,* Dr. E. E. Baumeister; *Censor,* Dr. D. H. Moulton.

The Fall River, Mass., Medical Society, at its annual meeting on December 9, elected the following officers: *President,* Dr. C. A. Howland; *Vice-President,* Dr. A. J. Barre; *Secretary,* Dr. R. W. French; *Treasurer,* Dr. W. S. Lyon; *Librarian,* Dr. G. L. Richards; *Assistant Librarian,* Dr. A. C. Macrae; *Executive Committee,* Drs. A. C. Lewis and F. A. Chace; *Program Committee,* Drs. J. H. Lindsey, W. H. Creamer, and Mary W. Marvell.

The Medical Society of Kent County, R. I., meeting at West Greenwich on December 11, elected the following officers: *President,* Dr. Benjamin F. Tefft, Jr., of Anthony; *Vice-President,* Dr. Philip C. Means of Apponaug; *Secretary,* Dr. Charles I. Phillips of East Greenwich; *Treasurer,* Dr. Frank Bailey Smith of Washington; *Censor,* Dr. James N. Bodwell of Harris.

Prof. Jean Alfred Fournier, the well known dermatologist and syphilographer, died in Paris on December 24, at the age of 82 years. He was a Commander of the Legion of Honor, a visiting physician of the Paris hospitals, a Professor of the Medical Faculty at Paris, and a member of the Academy of Medicine.

Obituary Notes.—Dr. Alexander P. O'Malley of Wilkes-Barre, died at his home in that city on December 12 at the age of 62 years. He was born in Ireland and was brought at the age of two years to New Haven, Conn., by his parents. He was graduated from the medical department of the New York University in 1876, and soon thereafter began the practice of his profession in Wilkes-Barre.

Dr. Johnston McLanahan of Chambersburg, Penn., a graduate of the Jefferson Medical College, Philadelphia, in 1865, and a member of the Medical Society of the State of Pennsylvania and the Franklin County Medical Society, died at his home on December 13, aged seventy years.

Dr. Clarence Howard Hagmeier died at Reinholds, Pa., on December 16 at the age of twenty-eight years as a result of septicemia. He was graduated from the medical department of the University of Pittsburgh in the class of 1913, and he resided for a time at Iselin, Pa.

Dr. John F. A. Clausnitzer of this city, died on December 20 at the age of 61 years. He was born in Dresden and obtained his medical degree at the University of Leipsic in 1881. He had practised in New York since 1883.

Dr. J. S. McCorkle died in his home in Fort Smith, Ark., on December 11, at the age of 79 years. He served in the Confederate Army as surgeon and since the war had practiced in Arkansas. He retired several years ago.

Dr. Thomas W. Flood died of typhoid fever at his home in Haverhill, Mass., on December 16. He was born in Nashua, N. H., in 1883 and was graduated in medicine from the Johns Hopkins University in 1902.

Dr. Winfield S. Smith of Boston died at his home in Brookline on December 16, at the age of 53 years. He was born in Chatham, Mass., and was graduated from the Boston University School of Medicine in the class of 1883. He was surgeon to the Massachusetts Homeopathic Hospital, the Westboro Insane Hospital, and the Leonard Morse Hospital in Natick. He was professor of operative surgery at the Boston University medical school and consulting surgeon to the Emerson Hospital.

Dr. Edward W. Myers, a retired physician of

Kansas City, died on December 14 at the age of 77 years. He was born in York County, Pa., and was graduated in medicine from the University of Maryland in 1862. He practised in Kansas City from 1881 until about two years ago.

Dr. HARRY T. WALDER, formerly of Camden, N. J., died at Dubuque, Ia., on December 15. He was a graduate of Jefferson Medical College and of Keokuk Medical College.

Dr. JAMES WINTER WAMSLEY died at Philadelphia on December 21 at the age of 40 years. He was graduated from Jefferson Medical College in the class of 1893, and he served afterward as resident physician in Cooper Hospital, Camden, N. J.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CHADWICK LECTURE—INJURIES IN WAR—ENTERIC FEVER IN WAR—GENERAL MEDICAL COUNCIL—ROYAL COLLEGE OF SURGEONS—LONDON HOSPITAL—NAILS REPRODUCED.

LONDON, December 12, 1914.

SIR RONALD ROSS delivered the first Chadwick lecture for this year on Friday last, taking as subject "Government Civil and Military Sanitation in the Tropics." He considered that the exclusion of civilization from large tropical areas was due to a considerable extent to diseases prevalent in such areas which had not been investigated until recently. We have now found out how many tropical diseases are caused and how they might be prevented, but the question remains whether public administration can utilize the measures suggested by science. The ancients took some care of sanitation, as witness the success of Empedocles in expelling malaria from a Sicilian city 500 years B.C. But in the Middle Ages nothing advanced. In modern times the history of sanitation began with that of colonization as diseases were encountered by the early voyagers and explorers who paid little attention to food, water, dress or housing. Towards the middle of last century some growth of sanitation in Europe was manifest, and that naturally extended to the tropics. Sir Ronald said the seven commandments of sanitary science were: Pure water supply, pipe sewerage, no vermin, efficient management of towns and villages, special measures against special diseases, adequate sanitary law and adequate sanitary organization. These were, he thought, beginning to be obeyed by governments and people in the tropics.

Sir J. Crichton-Browne, who presided, thanked Sir Ronald Ross and said sanitation was more than armaments. He also regretted that the antivaccination league was luring men into opposition to typhoid inoculation which was an undoubted protection.

Mr. Lockhart Mummery at the Royal Society of Medicine read a paper advocating expectant and conservative treatment in injuries to the bowel from shell or bullet wounds. He said the worst cases were those in which there was fracture of the pelvis or sepsis. He described a case of faecal abscess opened by a traumatic aperture through the ileum. The bowel was sutured and complete recovery followed. In such cases he thought temporary transverse colostomy was usually advisable.

Enteric fever in war has been discussed at the Society of Tropical Medicine and Hygiene, on the introduction of Sir William Osler, who treated it from several aspects, but chiefly in regard to the results of immunization as shown in the United States army. The figures he considered quite conclusive as to the benefits of antityphoid inoculation, and while admitting the possibility of unpleasant after effects said he found in cases brought to his notice only slight headache with rise of temperature the day after the injection and some diarrhea or perhaps constipation a day or two later. At present, cases from the front were few, he had only seen two or three at the Oxford base hospital, but the conditions of the war predisposed to an outbreak and it would be a triumph of sanitation if one did not occur.

The president, Sir Havelock Charles, expressed strong belief in inoculation and gave statistics of the Indian army showing the improvement since it had been employed. In India isolation stations for convalescents proved valuable against typhoid carriers. Sir John Broadbent referred to paratyphoid in relation to carriers. Dr. Walter Broadbent told of six cases of illness after inoculation; one of pneumonia the day after when feeling unwell he refused to lie up and caught a chill; four of pyrexia for a few days of men inoculated the same day, so possibly defective serum; one feverishness two days after second inoculation. Dr. Goodall was disappointed with the lack of news from the front, enteric being often prevalent in France and Belgium. He was sceptical about carriers, but believed in personal infection. Fleet-Surgeon Bassett-Smith reported free use of inoculation in the navy. He knew one case of a carrier taking typhoid from one ship to another. Dr. Atkinson said men ought not to be sent to the front too soon after inoculation; he knew of influenza and albuminoria coming on after inoculation. Dr. F. M. Sandwith had done more than 1,000 inoculations without any after ill-effects, and thought those reported must be due to want of care or exposure afterwards, as happened to some men taken next day for a route march. Rest for twenty-four to thirty-six hours should be insisted on after every injection. He questioned if the deltoid was the best site. So did Sir W. Osler, who in his reply recommended the pectoral or the abdominal wall, and endorsed what had been said as to rest and some other points.

The General Medical Council has concluded its session. Though a good deal of business was got through there is not much in the proceedings to interest your readers. Much of the time of the meeting was occupied by trying accusations of "infamous conduct in a professional respect," which is the form under which all charges of misconduct have to be made. So the only penalty in the power of the council is removal of the name of one found guilty from the "Medical Register," and that disqualifies him from practice. As this is too severe for minor offences, involving the ruin of the person, the council has invented for itself a minor punishment—a temporary suspension from practice. This is managed by postponing the decision until the next meeting of council when the accused has to appear again and bring evidence of his conduct during the interval. As he can during that time obtain the help of a qualified person to carry on the practice, though he will suffer great loss, no doubt in many cases he may, if eventually permitted, recover a number of his patients. Even so the sentence is heavy. Several were thus dealt with during the session and in one or two the full penalty of erasure from the Register was inflicted.

On a report of the executive committee it was decided to postpone for the present the visitation and inspection of examinations by the qualifying bodies.

A report on the examinations of the Apothecaries' Hall of Ireland led to a long unsatisfactory discussion. The representative of the Hall was able to quote reports of examiners to the council expressing favorable views as to the adequacy of the examinations. To listen to this and what followed, if you had some knowledge of the history of the different bodies here represented, might very well suggest that we knew very well that we have too many examining bodies, but each thinks his own is not the one that should be sacrificed. Few would deny that the majority could very well be spared. It was at length decided to send the report to the Hall and request their observations upon it, which postpones the matter until the next session in May, 1915.

Other committee reports were received and approved on: The public health, the pharmacopeia, students' registration, dental education, and prevention of unqualified practice. The last named desired that the council should convey to the Prize Council its complete approval of the recommendations of the select committee of the House of Commons on patent medicines and also represent to the Lord President the necessity for the immediate creation of a Ministry of Public Health in pursuance of the advice of the same select committee. The council adopted both these recommendations and concluded the session.

Yesterday at the Royal College of Surgeons the council decided that the Hunterian oration should be delivered as usual on the fifteenth of February, 1915, but that the dinner in the evening should not be held. Many other institutions are omitting their customary festivities during the war. At this meeting the recent resolution of fellows and members in favor of admitting members to direct representation on the council was considered. The council held that as the matter was fully considered last March they could see no advantage in reopening it at the present time.

The London Hospital has offered the Government to despatch to France a contingent staffed by physicians, surgeons, dressers, nurses, radiographers, and others. The contingent can start at once. At the meeting of governors when this offer was made it was stated that the cost of various drugs had increased since the war—carbolic acid, for example, had gone from 3¾ pence to 16 pence per pound. Sir F. Eve, after thirty years on the surgical staff, was elected a consultant. To the chairman, after nineteen years' service, the committee presented his portrait, which he in turn presented to the hospital. It was decided to cancel all festivities this Christmas.

Dr. Leslie Dunro mentioned at the Aesculapian Society the case of a woman of forty-five whose finger and toe nails had long been absent. She had to undergo ovariotomy. After the operation the nails began to grow rapidly and in three weeks were completely restored.

Parotid Ablation and Pluriglandular Insufficiency.—Lorenzo Neri has shown by experiments on dogs and rabbits that following extirpation of the parotids there are structural changes in the thyroid, ovaries, testicles, pancreas, suprarenals, spleen, and kidneys. These changes consist at first in a diminution in the tinctorial reactions, and later in an involution and atrophy of the respective organs with an intra- and extracellular fatty infiltration.—*Giornale Internazionale delle Scienze Mediche.*

4. The Present Status of Crotalin in the Treatment of Epilepsy. D. R. Thom
5. Trauma to the Kidney Resulting in Nephrectomy Report of Two Cases. W. E. Hartshorn.

1. Significance and Effect of Pain.—J. M. T. Finney in the Ether Day address states that his own clinical observations support the contention of Ross that there are two forms of pain, splanchnic and somatic. Any nerve ending may be sensitive to some one form of stimulation which has been called "the adequate stimulus" but insensitive to all others. The adequate stimuli vary for different parts of the body—therefore visceral pains are not of the ordinary tactile or thermal types to which the skin and mucous membranes so promptly respond. The threshold of pain may be raised or lowered according to certain established conditions. Tension in some form or other is the commonest, perhaps the sole cause of visceral pain. The referred pains arising in the course of disease of the internal organs increase the difficulties of diagnosis many fold. There is a psychology of pain. Some one has said that pain is the resultant of two factors, the lesion and the patient. It is difficult to estimate the degree of pain but there are certain signs of suffering which are unmistakable—the pinched features, the knotted brow, the rolling eyes with widely dilated pupils, the ashen countenance, the cool and clammy skin, the thready pulse, the increased blood pressure, the hands alternately clenched and opened, the cries and groans, and the bodily contortions—all these present a definite picture. The fear of pain plays a large part in its psychology. While on the one hand pain breaks down the powers of inhibition so that the individual who has at first exhibited fortitude becomes a complaining creature or one embittered or hardened, nevertheless on the other hand pain has an ennobling influence and brings out the higher qualities of heart and mind. Pain as a diagnostic sign is of the utmost importance. Ninety per cent. of all diseases either begin with it or at some time in their course are accompanied by it. Pain arising in inflammatory processes, particularly of bone, is described as "boring" or "throbbing" or "jumping" in character. Nerve pains are burning, shooting, or stabbing. The terms "stinging" or "sticking" describe the sensation experienced early in the course of cancer of the breast. The postprandial pain of gastric or duodenal ulcer, and the pain of anal fissure, increasing for several hours after defecation, are characteristic. Pain is notoriously worse at night. Weather conditions have an important effect upon pain. Individuals of the phlegmatic type bear pain better than others. Abdominal pain is usually accompanied by spasm of the overlying muscles. The sudden cessation of pain in the course of an acute inflammation of the right side of the abdomen may be of the gravest import, particularly if not associated with a corresponding drop in the temperature, pulse-rate and leucocyte count. Under these circumstances it is an unfailing index of gangrene or rupture of the appendix or of a sudden breaking down of the barriers between an abscess and the general peritoneal cavity. It is essential to the successful treatment of any case in which pain is a prominent feature to know when to withhold anodynes so as not to mask the clinical picture, and when to administer them.

2. Community Health.—G. M. Katsainos makes a plea for the more thorough teaching of venereal dis-

eases in the medical school; a wider education of the public regarding the horrors of these diseases; a suppression of quack advertising in the newspapers; the isolation of infected prostitutes; a boycott of the indecent drama; and the payment of better wages to the working woman.

3. Critical Defervescence in Typhoid Fever.—E. J. Wood calls attention to the rarity of crisis in typhoid fever. Curschmann has noted a so-called "pseudo-collapse" occurring during the height of the fever, but unattended by any alteration in the character and rate of the pulse. The *crise hypothermique* of the French is unaccompanied by collapse and is followed by a return of the temperature to the former level. In the presence of a sudden fall of temperature in typhoid fever it is necessary to exclude all possible sources for this drop, such as hemorrhage or perforation. According to the author's experience crisis in typhoid fever is not to be dreaded, for it is unattended by dangerous depression. Crises usually occur after a high run of temperature in cases of severe toxemia.

10. The Treatment of Chronic Leg Ulcers. Harry D. Sonnenschein.

1. Aphasia and Apraxia.—A. B. Evarts reports the case of a woman in whom these conditions were present. He notes that Frantz has described sixteen varieties of aphasia ranging all the way from cortical motor aphasia to member apraxia. The patient was able to say a few words and sentences voluntarily, but many of her attempts at speech could not be understood. When given a ring she named it correctly. A pencil she called a knife. Given a hairpin she called it a "cake, no ring," and then said, "What is that now? Tell me, I can't speak it." She was unable to write her name with either hand, making only a few purposeless movements. She could promptly follow simple commands when told to stand up, to cross her legs, squeeze the examiner's hand, etc., but any command containing two or more ideas brought about confusion and inability to obey. She was unable then to name certain pictures which were given to her, but recognized the correct name when it was supplied. In this case the aphasia is not pure. The power of expression by speech seems to have received the chief injury, but there were frequently noted times when words failed to provoke their proper engrams. There was an accompanying apraxia of the right hand and to a lesser degree of the right leg and a dyspraxia of the left hand. How great may have been the injury to that portion of the brain which exercises control over reading and writing was hard to say because the patient never could write anything but her own name. The author infers, therefore, that this was a cortical lesion. The trouble was motor rather than sensory, and Broca's center was the one probably affected, this being in the posterior portion of the inferior frontal convolution where it borders upon the operculum. An interruption of the association fibers alone was sufficient to account for what sensory disturbance was found as well as to account for the apraxia. Whether the actual lesion in any way involved Wernicke's center, which is in the left superior temporal convolution, and concerns itself with the tone pictures necessary to the understanding of speech, was difficult to say. The posterior portion of the inferior frontal convolution is inferred to be the area in which the lesion was present in this case.

2. Glénard's Disease.—O. Lerch has come to the conclusion that enteroptosis is due to an abnormal form of the spine and that hysteria, neurasthenia, and the visceral neuroses are caused by circulatory disturbances in this constitutional anomaly.

9. Sulphurous Acid in the Treatment of Furuncles.—P. G. Skillern, Jr., recommends the administration of one teaspoonful of this drug in a large glassful of water three times daily after meals. As much as three teaspoonfuls may be given. The mouth must be well rinsed after each dose; the remains of the acid in the mouth may be neutralized with milk of magnesia. The breath hould be held while the dose is being swallowed, for the fumes are slightly irritating to the respiratory tract. This method of treatment shortens the course of boils and prevents recurrence.

4. Mercurialized Serum in Treatment of Cerebrospinal Syphilis.—C. M. Byrnes describes the technique of this method as follows: Sufficient blood is withdrawn to yield from 12 to 30 c.c. of serum. The larger amount is obtained if concentrated serum is to be used. After the blood has coagulated the serum is pipetted, and if necessary the blood is centrifugalized for twenty minutes. If diluted serum is to be used, to 12 c.c. of the centrifugalized specimen is added 1 c.c. of a solution of mercunric chloride in freshly distilled water so made that each cubic centimeter contains 0.0013 gram of mercuric chloride. To the serum thus prepared is added a sufficient quantity of physiological salt solution to make a total volume of 30 c.c. If the concentrated serum is used this step is omitted. The serum is heated at 56° C. for half an hour and administered by gravity at body temperature. The author believes that the method is equally as efficacious as the use of salvarsanized serum. The immediate reactions following its administration are, in general, not so severe as those after the use of salvarsanized serum, and the cell count in the spinal fluid appears to be more quickly reduced. Since preliminary medication is not required, the blood may be obtained at any time; and because of the greater stability of the mercurialized serum it may be prepared at leisure and

kept in sealed flasks until it is convenient to administer it.

5. **The Suprarenal Glands in Delirium Tremens.**—E. F. Hirsch states that Le Count, a coroner's physician of Chicago, regularly found alterations in the cortex of the suprarenals in patients that had died from delirium tremens. The changes consisted in a diminution in the yellow color normally present in the cortex. In thirty-four cases studied by the author it was found that the doubly refractive droplets in the suprarenal cortex were diminished to a greater or less degree, or were even entirely absent.

6. **Autogenous Serum Treatment of Psoriasis.**—H. Fox finds a decided value in this method of treatment when it is used in conjunction with chrysarabin. The serum is injected intravenously, a method which is devoid of danger. The technique of the treatment is as follows: Fifty c.c. of blood removed from the cubital vein by means of a MacRae needle are allowed to flow into a sterile cylindrical glass bottle. The bottle and its contents are then properly balanced and placed in an electric centrifuge having a speed of eighteen hundred or more revolutions a minute. When the serum is thoroughly separated from the corpuscles and fibrin it is drawn off into a glass syringe and injected without delay, either intravenously or intramuscularly. The amount of serum that is generally obtained from the 50 c.c. of blood varies between 15 and 25 c.c., the latter being the maximum. In every case the serum is injected in an active state. As a rule the entire procedure of drawing the blood and injecting the serum is completed in half an hour or less.

15. **Phenol Injections in Hydrocele.**—R. H. Herbst points out that the common recurrences following the old method of injecting phenol without the preliminary washing out of the sac were due to the fact that the sac wall was covered with serum, which coagulated the phenol and did not allow the acid to come into contact with the sac wall. To obviate further such a contingency it has been the practice to test the return fluid for albumin and to continue the washing of the sac until the fluid fails to give a reaction to nitric acid. Then from 10 to 12 c.c. of 95 per cent. phenol are injected, the scrotum at the same time being manipulated so as to bring the acid into contact with all parts of the sac; then the excess is allowed to flow out, after which about 15 c.c. of alcohol are injected. The injection of sterile water into the sac serves the double purpose of cleansing the sac wall and prevents the not infrequent accident of injecting the phenol into the tissues of the scrotum. During the emptying of a well-filled tunica vaginalis the receding sac wall is likely to draw away from the end of the cannula without the knowledge of the operator. If this does occur and the water is injected, it does not return, but remains in the tissues of the scrotum, which appear edematous. Under such circumstances the sac must be allowed again to fill with serum before an attempt is made to inject the phenol. The use of the Belfield hydrocele trochar and cannula, however, practically always prevents this accident because it fixes the sac, by passing through two of its walls. The refilling of the sac which is commonly seen during the first twenty-four hours after the injection is due to the reaction of the tissue to the phenol and disappears spontaneously within a few days.

5. Experiments in the Germicidal Action of Colloidal Silver. W. J. Simpson and R. T. Hewlett.

1. Problems in Mental Pathology.—E. Goodall in his second lecture on this subject discusses such topics as the ductless glands and mental disease, the toxicity of fluids in the insane, and leucocytosis in mental disorders. As regards the bacteriology of the feces in acute mania and melancholia researches have shown that there is an increase in the total number of organisms and of *Bacillus coli* in the great majority of the cases of mania, and in rather more than half the cases of melancholia; a diminution in the anaërobic organisms investigated in the great majority of the mania and the majority of the melancholia cases; a considerable diminution (or absence) of aërobic spores in both kinds; an absence of atypical *Bacillus coli* and of unusual organisms in both kinds. Lastly, these cases afford no evidence that *Bacilli coli*, even though present in abnormal quantity, exercises any influence in the conditions dealt with. As regards leucocytosis in insanity the studies show that in the earlier phases of dementia præcox there is a moderate increase in the total white cell count with a relative increase of the neutrophiles. At the beginning of an attack of acute mania or melancholia there is a leucocytosis with an increase of the neutrophiles. In puerperal insanity the leucocyte counts resemble those of acute mania.

4. Suicide and Insomnia.—C. E. Pronge refers to the frequent association of insomnia and suicide as cause and effect. The insomnia is in many instances to be attributed to slight errors of refraction.

4. Leeches: Exotic Leeches. H. E. Shipley.

3. Acute Appendicitis and Acute Appendicular Obstruction.—D. P. D. Wilkie concludes that two acute pathological processes are met with in the vermiform appendix—acute appendicitis and acute appendicular obstruction. Clinically acute appendicitis is distinguished by the signs of inflammation, there being from the onset a rise in pulse and temperature. Acute appendicular obstruction gives rise to vomiting, colicky pain, and abdominal tenderness, but at the outset to no appreciable rise in pulse or temperature. The changes occurring in an appendix the lumen of which is completely obstructed depend on the presence or absence of fecal matter within its lumen. In experimental obstruction in an artificial appendix the changes vary greatly according to the nature of the diet of the animal previous to the experiment, rich protein diet being associated with much more rapidly destructive changes than carbohydrate. Undigested protein, putrefactive bacteria, and an alkaline reaction together produce rapid gangrene in the walls of the obstructed organ. The prevalence of the severer forms of acute appendicular disease in Western as contrasted with Eastern peoples is probably to be explained by the animal diet indulged in by the former. On the same lines may be explained the increasing frequency of such disease in large industrial areas and its relative frequency in the male sex.

5. The "Elderton" Method of Control in Testing the Value of New Tuberculin. H. Patty Shaw.
6. Artificial Pneumothorax. H. de Carle Woodcock and J. A. M. Clark.

1. Transient Paraplegia from Shell Explosives.—T. R. Elliott describes this condition as follows: Numbness and complete paralysis of the legs are complained of when the injured man receives help from his comrades immediately after the explosion, and yet there is no manifest wound of the body. The arms are generally unaffected, but the legs remain powerless, so that the patient has to be carried from the field on a stretcher. Within a week movement and sensation are returning in the legs, and after the lapse of a fortnight the soldier as a rule can walk about again, though he continues to complain of extreme tenderness in the lumbar region and aching pains that shoot up the back. There is rarely any trouble with the sphincters. During the paralysis the leg muscles are slightly flaccid, and both the superficial and deep reflexes are depressed, while there is nearly always an area of hyperalgesia encircling the abdomen above or below the level of the umbilicus. The plantar reflex is never extensor. Two theories have been advanced to explain the cause of this condition. One explanation is that the paraplegia is functional and the residual tenderness is neurasthenic. The second tentative diagnosis is that of "gassing," a toxic action of the fumes evolved in the explosion.

4. Incipient Pulmonary Tuberculosis of School Children.—W. Overend states that the coexistence of the five conditions: (1) Intermittent sudden cough in the absence of cases of pertussis; (2) wasting, pallor, and tiredness; (3) a subfebrile temperature rising occasionally to 100°; (4) the presence of capillary veins and a growth of hair over the upper thoracic spines; and (5) the absence of any obvious disease should induce the physician to examine carefully for pulmonary tuberculosis and enlarged bronchial glands. The *x*-rays may be helpful in the diagnosis.

Berliner klinische Wochenschrift.

November 23, 1914.

Nervous Disorders in Children.—Katz speaks of the remarkable cumulation of a relatively uncommon condition which he has recently seen. First there was a series of phobias such as are common in adults but almost unknown in childhood. In the last four weeks he has seen five such cases, all in girls from six to ten years of age. Two patients were "only children." The clinical picture was as follows: Children originally in perfect health began to look ill. They were pale, flabby, the facial expression indicated fatigue mixed with melancholy. Appetite failed. From time to time play was abandoned and instead there was revery or aimless restlessness. After an interval of five to fifteen minutes they resumed their usual activities. One very active girl of six years ceased playing altogether. Two of the patients complained of vertigo for which no organic cause could be found. The theory of some parents was that the children had been greatly shocked by the war, and the author succeeded in eliciting that this cause inhered in all the cases. Not the mere idea of war, but the recital of details, especially of deeds of cruelty, which they were told or which they overheard. Four of the five children had nervous parents, but no real taint was present. The other child had a severe taint, her mother being probably a paranoiac. All of the children told about the same story. They were suddenly thrown into a state of anxiety and remained thus for a short time, whereupon the seizure terminated. Two patients developed these phobias when they chanced to think of some cruel deed of the sort mentioned, but the others could assign no reason whatever for their seizures. All the children come from the better classes. The one with the bad taint happened to be the only one whose father is in the field. This one each evening at bedtime begins to cry out "I am so afraid!" The darkness plays no part in causing the fear, nor is the latter the ordinary pavor nocturnus. The mother must sit with her for two or three hours before the child is quieted. Her sleep is very restless. The prognosis was apparently good in all but the case just mentioned. The treatment was purely psychical. The tales of cruelty had caused psychic trauma. The author has also noted a number of cases of enuresis nocturna and pollakiuria in both sexes.

Fungous Disease of the Skin from Woolen Underwear.—Isaac describes a dermatosis which bears a strong resemblance to ordinary ringworm, and appears in the late autumn. The affection agrees with that variously termed pityriasis rosea and herpes tonsurans maculosus, clinical affections for which parasites have never been described. The lesions consist of oval macules which come out in great numbers and when their centers are scratched with the curette show a certain scaling. The affection may be confounded with lues and psoriasis. It yields readily to red sulphide of mercury ointment of 10 per cent. pyrogallic acid ointment. The chief point of interest is an unsuspected relation between the disease and the wearing of woolen sweaters. But the lesions in these cases differ slightly from the typical eruption in being localized, the lesions clearing up in the centers and a much higher degree of itching present. The author is convinced that some unknown fungus is carried by the wool. The latter as a rule is laid by in the summer and evidently becomes contaminated by some fungus. All woolen garments should therefore be sterilized before wearing, using ordinary soap and hot water and drying carefully. In view of the warfare going on attention to so small a matter should be well repaid by the great relief in suffering for the troops.

Münchener medizinische Wochenschrift.

November 17, 1914.

Treatment of Tetanus.—In the military supplement of this number of the *Wochenschrift* are to be found six articles on this subject. Professor Hochhaus of Cologne states that we now have enough material to test all plans of treatment, to note initial symptoms, and in all respects to correct any false teachings now in our text-books. The infection begins with vague sensations in the face or neck, and ofttimes a tickling in the throat suggests a beginning angina. One set of symptoms may point to the face and mouth, another to the throat, a third to the nuchal region, etc. Other prodromes are seated in the injured members. In regard to the latter the author states that he has amputated five times for bad wounds of extremities without preventing the subsequent appearance of tetanus which destroyed all but one of the lives. This he regards as a document that amputation as a preventive of tetanus is not indicated. In regard to serotherapy the latter was tested in relatively large doses in a material of twenty-two cases of severe tetanus. Of eleven of this number who received large timely doses of serum four patients were saved, but the seven who died represented the seven severest cases. Taking the entire series of twenty-two, the survivors, eight in number, seemed to owe their recovery not wholly to the serum but in part to the mild degree of symptoms. Still a recovery of over one-third of cases thus treated would argue that serum injected early and in large quantities is a factor in recovery. At any rate the author incorporates it into the general

treatment of the disease. The author also treated a series of seventeen severe cases with magnesium sulphate in conjunction with serotherapy. In this series there were twelve deaths and five recoveries (60 per cent. recoveries). Bacelli's method was tested in fifteen cases with 60 per cent. recoveries. These cases were, however, mild in character. At present his attitude is as follows: he would injust serum, if necessary into the cord and nerve trunks and give magnesium sulphate and morphine for the symptoms. Kreuter gave the serum a grand tryout in a series of thirty-one cases. It was injected into the cord and blood in very large doses, and what is termed the mortality under the proper use of serum was reduced from about 60 to 35 per cent. A higher mortality is therefore held to be due to defective technique in serotherapy. Other remedies played but a very minor rôle in this series. Müller gives hot baths in the less severe cases of tetanus and makes considerable use of mild anticonvulsivants. In regard to serum and magnesium he is unable to convince himself of their value. Serum is too expensive. The author defends the practice of tracheotomy in cases with threatening spasm of the glottis—evidently, however, only when death seems imminent. He believes that he has saved at least one life thus. Rothfuchs mentions the alleged successful treatment of severe cases of tetanus under the use of serum and magnesium, carbolic acid and peritoneal transudates. But there have also been reported series with fearful mortalities where serum or magnesium was freely used. He has seen apparent benefit from salvarsan, for that matter. His complete experience with the disease is as follows (six cases): I—Type severe, incubation fourteen days. The wounded foot was amputated and serum given *ad lib.* Nevertheless the disease went on to spasms of the diaphragm. There was no serum on hand, so that a dose of salvarsan was injected by a vein. The improvement was startling, and from that time the patient was out of danger. II—Case quite similar to preceding. Recovery. It would be called of medium severity. III—Severe type. Incubation thirteen days. No serum available, so that salvarsan was substituted. Later serum arrived and was used freely. There was slow recovery. IV—Case fatal from intercurrent pneumonia, although patient died with trismus. This patient received serum and salvarsan *ad lib.* V—Medium, incubation thirteen days. Received serum and salvarsan *ad lib.* and made a good recovery. VI—Severe, nine days' incubation. Serum and salvarsan given *ad lib.* Good recovery. In other words the author's series of six cases gives a mortality of but 17 per cent. and some of the life-saving must be set down to salvarsan. The author has taken pains to have his serum-salvarsan tested in future cases. Alexander writes up a series of ten cases with eight recoveries. Credit is given to the immense doses of chlorad hydrate used. The first two patients who received small doses died. Afterward the dose was doubled. Serum was given in moderate quantities, doses according to severity. All of the chloral was given by enema.

Deutsche medizinische Wochenschrift.

November 19, 1914.

Treatment of Severe Cases of Tetanus.—Kocher concludes his serial article on the use of magnesium sulphate as follows: This substance is at present the most important remedy against tetanus. Its action is, fortunately, transitory, and comprises anesthesia and muscular relaxation. The former result increases with the concentration of the salt; the intralumbal injection causes a local dehydration of the cord and nerve roots, which should have no ill consequences. Only the full dose can be counted upon to do the work, so that in failure we must continue to inject even until the potential of the tetanus toxin is exhausted. The author has given as many as ten consecutive intradural injections. The duration of the subcutaneous action depends on the dose; it is often possible to maintain the desired dose with a minimum of substance. When confronted with a case of the disease a trial dose of magnesium sulphate should be injected subcutaneously, and if this produced favorable results the remedy should be pushed by this route rather than by a change to the intraspinal method. The war furnishes ample opportunity to test the subcutaneous route by injecting after each exacerbation. The remarkable results in tetanus neonatorum recently reported appear to justify this procedure. On the other hand the author's remarkable series of cures in adults was brought about by the intraspinous use of the remedy conjoined with tracheotomy and intratracheal insufflation of oxygen. Kocher now lays down a special series of indications for the use of magnesium. In mild cases with initial symptoms of local increased tendon reflexes, dysphagia, mild trismus, etc., serum should be used to block off the infection. Ten ccm. should be infiltrated about the wound field and the (exposed) muscles. Endoneural blocking should be employed if practicable and 10 ccm. of serum injected into the dural sac after the withdrawal of the same quantity of the intraspinal fluid. The wound is naturally given complete aseptic treatment. Then in strong men from 30 to 45 ccm. of a 25 per cent. magnesium-sulphate solution should be injected subcutaneously to relax the muscular rigidity and diminish the reflex excitability. At the same time large doses of chloral hydrate should be given, as much, if required, as 12 gms. in twenty-four hours. The preceding measures refer to moderately severe cases. If the degree is more severe in that arrest of respiration is to be feared, magnesium should be thrown into the cord, 10 ccm. of a 15 per cent. solution, the body kept horizontal, the head held up. If no impression is made on the symptoms in fifteen minutes the head should be lowered and one should be ready to combat any tendency to respiratory arrest by the presence of a tracheotomy outfit and oxygen. More serum may be required. If the case shows no signs of improvement magnesium must be pushed intralumbally with gradually decreasing dose, or subcutaneous injections with chloral may be renewed.

Alcohol in the Field.—Schwalbe states that the great war is causing changes in values in the minds of people. Most of the nations banished the use of alcohol from the time mobilization began. This proscription seemed to involve no hardship, but somewhat later there was a demand for alcoholics, round robins having been sent out by the troops. A propaganda for stimulants was inaugurated, certain telegrams from officers in regard to a supply of liquor were made public, and as usual liquor dealers were opposed to "whipped cream lickers" and "coffee patriots." The average demand seemed to be for Jamaica rum. One of the German temperance societies communicated with the Crown Prince, who was believed to have been responsible for letting down the bars, but the latter replied that rum had been requisitioned purely for medical uses. The upshot of the entire matter was naturally that grog rations or any equivalent were bad for the army as a whole, although when the problem was applied to the individual varying degrees of tolerance were found. The policy of using alcohol in borderline cases between health and illness, as a preventive of certain diseases, and as part of the treatment of established diseases cannot be settled to the satisfaction of all. The expense of supplying spirits to armies would be very great.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

INFLUENCE OF BUILD ON MORTALITY.

EXPERIENCE proves that men of the average standard of weight and height have better chances for resisting disease and living longer.

Underweight.—The increasing ratio of mortality with the decreasing weight at the younger ages of entry, as well as the decreasing influence of underweight with the increase of age at entry, are noticeable in table No. 1, compiled by the Medico-Actuarial Investigation Committee.

TABLE NO. 1. MEN—UNDERWEIGHTS.

ALL POLICY YEARS COMBINED, RATIO OF ACTUAL TO EXPECTED DEATHS.

Ages at Entry	VARIATION FROM AVERAGE WEIGHT IN POUNDS		
	−5 to −10	−15 to −20	−25 to −45
20–24	107%	115%	134%
25–29	99	108	116
30–34	104	100	108
35–39	91	103	102
40–44	85	87	97
45–49	97	99	89
50–56	90	92	91
57–62	93	82	81

Some allowance must be made in the figures of these tables for the modification due to careful selection. Underweight has long been considered an important feature at the younger ages, so that it may be assumed that great care has been exercised in selecting underweights at these ages, even though the results disclosed by the table remain unsatisfactory. On the other hand, it is seen that underweight among persons over 40 years of age is in itself no disadvantage.

Underweight, especially when combined with digestive disturbances or a poor family history, is a fairly immediate and decreasing hazard and is, therefore, an element which is difficult to provide for in the way of substandard insurance except through the lien system.

Overweights.—Table No. 2 of the Medico-Actuarial Investigation Committee suggests that overweight to a moderate degree is not a serious impairment at the younger ages of entry, but has a material effect at and after the middle ages. When, however, men were unduly fat before puberty, they should be regarded as poor risks, especially if they inherited the obeseness.

TABLE NO. 2. MEN—OVERWEIGHTS.

ALL POLICY YEARS COMBINED, RATIO OF ACTUAL TO EXPECTED DEATHS.

Ages at Entry	VARIATION FROM AVERAGE WEIGHT IN POUNDS			
	+5 to +10	+15 to +20	+25 to +45	+50 to +80
20–24	96%	96%	101%	103%
25–29	93	90	112	117
30–34	99	86	119	134
35–39	100	101	131	155
40–44	94	110	140	175
45–49	103	109	131	151
50–56	102	121	124	149
57–62	102	125	112	138

The mortality among those more than 20 lbs. overweight is an increasing percentage of the normal mortality at the earlier ages of entry, reaches a maximum at ages 40-44 and a diminishing percentage at the older ages. The lower mortality among the older overweights is undoubtedly due to the great care in selecting risks at these ages.

The Medico-Actuarial Table unfortunately pays no attention to the distribution of the weight as shown by the relation of the weight to the chest and abdominal measurements. No man ought to have an abdominal measurement in excess to that of his chest. The predisposing causes of this unnatural enlargement are sedentary habits, excessive imbibition of liquids and a plentiful farinaceous and fatty diet. Abdominal protuberance, due to excessive indulgence in liquids, is common among Germans, French, Belgians and Dutch. Italians and Spaniards get stout and flabby owing to inactive lives, and farinaceous and oily diets. Observations prove that overweights with an excessive abdominal measurement are decidedly poorer risks than those with a measurement less than the chest.

Overweight is an increasing hazard and, unless too excessive, may be taken care of by an endowment or a rated-up policy.

Height.—The height of a man seems to have little effect on the rate of mortality, until it exceeds the extremes which may be set at over 75 and under 60 inches. The extremes have proved a short-lived class and die out of all proportion to their expectation after the age of 55.

The Medico-Actuarial Investigation Committee have not considered the extremes in heights but even in the records made up from those of 5 feet, 3 inches to 6 feet, 2 inches, there is a significant difference in the mortality.

TABLE NO. 3. ALL POLICY YEARS COMBINED.

RATIO OF ACTUAL TO EXPECTED DEATHS—MEN.

Ages at Issue	Height 5 Ft. 3 In. to 5 Ft. 6 In.	Height 5 Ft. 7 In. to 5 Ft. 10 In	Height 5 Ft. 11 In. to 6 Ft. 2 In.
20–29	96%	110%	122%
30–39	107	109	113
40–49	110	109	120
50–59	108	109	101

From table No. 3 it is seen that at the younger ages, tall men have proved less desirable risks than the short men. At the older ages, the taller men seem to have fared better, but it is probable that this better result is one of the freaks that will creep into statistics. In a general way, it can be stated that a tall, stout man is a worse risk than a short, stout man of comparatively equal weight.

Dr. William M. Brumby of San Antonio has been appointed assistant medical director of the Amicable Life Insurance Company of Waco, Texas, *vice* Dr. J. M. McCutchan, deceased. Dr. Brumby was for four years medical director of the Equitable Life Insurance Company of San Antonio and has also served as State health officer and as health officer of Houston.

The Medical Aspects of Accident Insurance.—An address on the "Medical Aspects of Accident Insurance" was delivered by Dr. W. C. W. McDowell in the Chamber of Commerce, Auckland, under the auspices of the Insurance Institute. The medical aspect of accident insurance, he said, was more complicated than the surgical aspect, the latter being more easy to follow, as the *x*-rays threw such a light upon injuries requiring surgical aid. He dealt with some of the problems presented in cases of heart strain, apoplexy, and hernia as being particularly interesting from the medical aspect of accident insurance, and made a strong plea for the appointment of medical referees to hear compensation cases in which the position depended on the medical evidence.—*The Australasian Medical Gazette.*

Book Reviews.

Sclerocorneal Trephining in the Operative Treatment of Glaucoma. By Robert Henry Elliot, M.D., B. S. Lond., Sc.D. Edin., F.R.C.S. Eng., etc., Lieut.-Colonel, I.M.S., Superintendent of the Government Ophthalmic Hospital, Madras; Professor of Ophthalmology in the Medical College, Madras; Hon. Fellow of the American Academy of Ophthalmology; and Hon. Member of the Minnesota Academy of Ophthalmology, of the Chicago Ophthalmological Society, and of the Detroit Ophthalmological Club. First Edition, 1913. Second Edition, 1914. Price, $3.00. New York: Paul B. Hoeber; London: George Pulman & Sons, Limited.

The second edition of Col. Elliot's work, appearing so shortly after the first, attests to the interest that is taken in the subject and the desire that opthalmologists have to better equip themselves for the treatment of glaucoma. The volume is one of 187 pages, fully illustrated, and with a very complete index. The work has been practically re-written since the appearance of the first edition. Col. Elliot has gone into the subject of trephining in glaucoma very thoroughly. A brief reference to the history of the operation is followed by a chapter on the newer operation for glaucoma; the indications for the operation; the technique of trephining after the method of Col. Elliot; the complications met with; after treatment; results; experiences of other surgeons than himself; modifications introduced by other surgeons; statistics, etc. Ophthalmic surgeons are deeply indebted to Col. Elliot for the introduction of and insistence on an operation that has proven to be of such great value to humanity. The book should be in the possession of all ophthalmic surgeons.

A Clinical Study of the Serous and Purulent Diseases of the Labyrinth, by Dr. Erich Ruttin, Privatdocent in the Otological Clinic University of Vienna with a foreword by Prof. Dr. Victor Urbantschitsch, authorized translation by Horace Newhart, A.B., M.D., Instructor in Otology, University of Minnesota; Otologist and Rhinologist, Northwestern Hospital; Fellow American Academy of Ophthalmology and Oto-Larynology; Fellow American College of Surgeons, etc. With 25 textual figures. Price, $2.00. New York: Rebman Company, 1914.

This very excellent book is a practical treatise of the subject of labyrinthian disease, with recent progress in the diagnosis and treatment of its complications. It consists of a detailed description of the diseases of the labyrinth, in which the functional manifestations of the normal and diseased labyrinth, the different clinical aspects, and the therapeutic considerations in each case are discussed and presented in a manner comprehensible even to the non-specialist. Of great interest are the brief though complete case histories.

A Text-Book of Military Hygiene and Sanitation. By Frank R. Keefer, M.D., Lieutenant-Colonel, Medical Corps, United States Army; Professor of Military Hygiene, United States Military Academy, West Point. Illustrated. Price, $1.50 net. Philadelphia and London: W. B. Saunders Company, 1914.

This book, dealing with a subject that is now of vital importance to half the world, gives a logical exposition of those topics of hygiene in relation to a large body of men which would appeal to the layman. It is well illustrated, treats of the care of troops in the aggregate in times of war and peace. The major part of the book is devoted to personal hygiene, and the general topics of water supply, food, disposal of wastes, etc. Short sensible chapters on the venereal diseases, alcohol, and other narcotics complete the book. With a clear comprehension of these matters, everyone can then determine for himself what his relations with these topics shall be.

Über die Ernährung des Auges. Von Dr. Med. C. Hamburger, Augenarzt in Berlin. Mit 26 Textabbildungen und 8 Farbigen Tafeln. Leipzig: Verlag Von Georg Thieme, 1914.

This work which is published is a brochure of 117 pages with a number of figures in the text, and five colored plates, has been conducted in a thorough and comprehensive manner, and presents all that is known to date on this subject. The author has made himself conversant with the work of others and has analyzed their results. He fully reports his findings after exhaustive, more or less original, research work. Part one has to do with the source of the intraocular lymph flow. Part two on the course of the lymph streams. Part three on the avenues of escape of lymph from the interior of the eye. The work represents a very careful study of the subject, and will well repay perusal by those who are interested in ophthalmology.

Local Anesthesia. By Dr. Arthur Schlesinger. Berlin. Translated by F. S. Arnold, B.A., M.B., B.Ch. (Oxon). Illustrated. Price $1.50 net. New York: Rebman Company, 1914.

This book of about 200 pages is designed to enable those who have no opportunity to gain acquaintance with the various methods by observing them in actual practice to perfect themselves in the technique by proceeding gradually from the simpler to the more difficult tasks. The author has thus attempted to put before the reader what he has found by experience to be the most simple and yet practical method. Beginning with a short review of the history of the development of local anesthesia and the physical principles involved, the author soon passes to the consideration of the materials used, adjuvants in local anesthesia, such as cold and anemia, and the methods of producing local anesthesia and their application. About 75 pages are devoted to these introductory chapters, the balance of the book covering general technique and the application of the various methods in the anesthetization of special regions and tissues of the body. The descriptions are simplified as far as possible and the novice in the use of local anesthesia should find the book most useful, though if success crowns his efforts in the simpler operations he will probably soon feel the need of a larger work where technique is given in greater detail.

A Textbook of Pathology for Students of Medicine. By J. George Adami, M.A., M.D., F.R.S.; Strathcona Professor of Pathology, McGill University, and Advisory Pathologist to the Montreal General and the Royal Victoria Hospitals, Montreal, and John McCrae, M.D., M.R.C.P. (London); Lecturer in Pathology and Clinical Medicine, McGill University, Montreal. Second Edition. Price $5.00 net. Philadelphia and New York: Lea & Febiger, 1914.

In this new edition which appears only two years after the first, the necessary changes have been made to bring the text up to date. There appear also one or two new features which deserve comment. A new chapter on "The More Important Infections and Their Prominent Features" contains material which was scattered throughout the first edition together with a mass of new material. The classification of tumors has been considerably simplified, the authors dividing all neoplasms into teratomas, teratoblastomas, and blastomas. While, of course, much can be said against such a classification, still it is an exceedingly useful one and the simplification is a distinct advantage. Recent work in toxins and the effect of "split products" are considered and the chapter on "Monstrosities and Abnormalities" has been placed in an appendix where it really belongs. The revisions embodied in this edition make the work more valuable than ever to the student and also, it may be said, to the practitioner.

Kirkes' Handbook of Physiology. Revised and Rewritten by Charles Wilson Greene, A.M., Ph.D., Professor of Physiology and Pharmacology, University of Missouri. Eighth American Edition. Price $3.00 net. New York: William Wood & Company, 1914.

The new edition of this standard textbook will be welcomed on all hands. Its position is too well assured to fear any criticism. This edition contains new material, especially along the lines of internal secretion, and retains some of the features of the older editions which are at least open to criticism. In his preface the author says, "Under present day conditions, the determining pedagogical horizon includes not only the subject matter of physiology, but that of the field of clinical medicine and surgery for which physiology furnishes the foundation." The reviewer feels that the field of the book has been widened to its detriment. For instance, a large space is devoted to uranalysis, while the physiology of the kidney is cut rather short. In these days when we have books on clinical pathology and special courses in that subject, why not leave all clinical pathology out of our physiology? An attempt to include both causes an abridgement of both. Still no one will question the great value of the work, both to teachers and to students.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 3, 1914.

THE FIRST VICE-PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS meeting was arranged by the Section on Otology.

Open-Air versus Open-Window Classes.—The COUNCIL OF THE ACADEMY presented the following report and recommendations. By open-air classes was meant classes of children taught in specially constructed rooms or houses which were practically open-air pavilions. By open-window classes was meant classes taught in regulation rooms of school buildings, but where the windows had been altered to open on pivots, thus securing the full benefit of the window openings, and where these windows were kept open all the time. It was understood that classrooms of both types were designed for children who were anemic or below par in physical condition. One of the main features desirable in these classes was a relatively low temperature, probably best ranging from 40° to 50° F. There was no evidence to show that any increased advantage was obtained by temperatures below 40° F. It was also desirable to maintain a relative humidity more nearly normal than was usual in steam-heated rooms, and, in addition, adequate but not excessive air movement. A maximum amount of sunlight in the winter months was desirable, and protection from the sun, preferably by awnings, in the spring and autumn. Freedom from dust and noise was important, and for that reason rooms should be at least three floors from the ground. In winter more protection from wind and draft was needed, while in spring and autumn the maximum of air movement that could be obtained was usually desired. In addition to these physical conditions it was understood that there should be a special régime providing for more relaxation from the strain of regular classes, and increased periods of rest. Adequate clothing for the comfort of the children was also understood to be necessary. Objections to open-air classes were: (1) That there was needless and possibly harmful exposure to cold in winter and to storms in all seasons. (2) That there was too great exposure to sun and heat in the spring and autumn. (3) That the cost of construction and equipment was considerable. It had been found that the cost per child for construction and equipment in the Chicago public schools was twenty dollars, as against five dollars per child in the open-window rooms. The objections to open-window rooms were: (1) There was too little air in movement in the spring and autumn. (2) There was too great exposure to the sun in the spring and autumn, because of the southern exposure of such rooms. This objection, however, could be adequately met by awnings. (3) There was an unequal distribution of air movement in the room, particularly in winter, exposing the children near the windows to too great drafts and cold. All these objections seemed to be of minor importance. A comparison of the results in the physical condition of the children seemed to show that probably the best results had been obtained in open-air classes situated in the country or small towns, where suitable and inexpensive types of construction were possible, and where facilities for exercise and play in the open immediately adjoined the schoolroom. The forest schools of Germany were ideal examples of this class of school. Reports based on a careful study of the results obtained in the improved physical condition and increased mental efficiency of the children in large cities showed a slight balance in favor of the open-air classes. These reports however, did not indicate sufficient difference to demonstrate any marked superiority of open-air classes over the open-window classes. The conclusion reached was that in the public schools of large cities the provision of open-air classes presented considerable difficulties and objections, especially in a climate with such variations of temperature as obtain in New York City. Consequently, inasmuch as the money available for fresh-air classes was limited, and the expense for the construction of open-air classes very considerable, the Council recommended that the Board of Education provide a large number of open-window rooms with pivoted windows and suitable awnings, rather than to so-called open-air rooms. They also recommended that the Board of Education encourage the practice among teachers of opening the windows in all regular schoolrooms.

Metastatic Conditions Complicating Suppurative Otitis Media with Special Reference to Secondary Inflammatory Processes in the Joints.—Dr. SEYMOUR OPPENHEIMER presented this paper. He stated that diseases of the ear maintained close relations with the body as a whole, and that a suppurative otitic process might give rise to secondary lesions remote from the focal point of infection. These were in the nature of metastatic processes. Their general symptomatology was that common to all cases of infective thrombosis. In addition to the general symptoms others arose according to the location of the metastases in the abdomen, the cranial cavity, or whether they were locally evident, such as cutaneous lesions, or cardiac, or in the joints and muscles. The course of the temperature might be so like that of typhoid fever as to lead to a wrong diagnosis. Two such cases had been reported by Dr. E. Libman in a paper read before the International Otological Congress. The first patient was a woman admitted to Mount Sinai Hospital with the clinical diagnosis of typhoid fever. The spleen was palpable, and there was a roseola and high remitting temperatures. Five weeks previously there had been an acute suppurative otitis, now completely subsided. The blood cultures were positive. A mastoid operation was performed and a perisinuous abscess and thrombosis of the sinus and of the upper part of the jugular vein was found. The second case gave a history of profuse aural discharge with high temperatures. The mastoid symptoms were most indefinite. The spleen was palpable one inch below the free border of the ribs. The blood culture was positive and operation revealed a mastoid filled with pus and thrombosed jugular vein. Dr. Libman in commenting on these cases designated them as being of a type that raised the question of the differential diagnosis between typhoid fever and an infection of doubtful otitic origin. They had observed three pulmonary cases in which an infective pleuropneumonia developed after a mastoid operation and complicated by a sinus thrombosis. These cases all died. Two cases of endocarditis secondary to otitis had also come under his observation. The cerebral cases were those in which there was development of a suppurative meningitis or extradural or subdural abscess. Whether these could be construed as direct metastases was open to question; more likely they were in the direct nature of a complication arising by contiguity. The cutaneous symptoms were manifested by petechiæ or ecchymoses and the ocular by purulent processes of embolic origin. Abscesses in the kidney and spleen could only be considered in the nature of a general bacteriemic process. Abscess in the muscles, and more particularly in the subcutaneous connective tissues, were not infrequent, and their symptoms were objectively and subjectively local. Seth MacCuen Smith of Philadelphia had described three cases of hepatic abscess occurring in the course of suppurative otitis media and mastoiditis, in none of which could he determine the existence of a sinus thrombosis, although the symptomatology was very suggestive. The writer said that he was at a loss to explain the development of these metastatic lesions without a sinus thrombosis and general bacteriemia being present, unless one reverted to the theory of Kearner on the osteophlebitis of the temporal bone causing direct absorption of septic material into the circulation from spaces in the bone. He was also at a loss to explain a case of acute appendicular inflammation and three cases of gall-bladder inflammation, all occurring in his practice, and following within two weeks after an acute mastoiditis. In none of these cases was there a sinus thrombosis, nor were the laboratory findings complete so that he could not state whether the same organisms were found in the diseased appendix and gall bladder that were recovered from the mastoid. In considering arthritic inflammations resembling acute rheumatism the writer said that eight cases had come under his observation in which symptoms were manifest which allowed of the recognition of the otitic basis of the infection, but in five cases the ear symptoms were so slight, or not referred to at all, so that a medical attendant might have completely overlooked the etiological disease, namely a sinus thrombosis. The characterization of acute articular rheumatism as a genuine disease, while still held by many clinicians, was energetically combated by many others, who believed that various microorganisms were able to produce the typical picture of acute articular rheumatism. Among those who had produced evidence supporting this view were Chostek, Sahli, Budy, Singer, Rosenow, Poynton and Paine, Cheadle, Netter, Lanz, Margaliano,

and others. Animal experimentation had undeniably demonstrated that weakened pyogenic cocci could produce the picture of articular rheumatism, and one could understand that as a complication of middle ear suppuration and infective phlebitis, symptoms of joint inflammation might exist, which symptoms might be so prominent as to overshadow the original causative disease. The writer then reported in detail the five cases above referred to in which an otitic thrombosis had its clinical history completely masked by the existence of an acute arthritis. In the second case the joint symptoms were associated with an endocarditis which improved sufficiently to allow the patient to go to work and was followed by a relapse of the joint swelling. In two of the other cases a number of joints became involved in turn, which, peculiar to say, were in a measure improved by specific remedies. In the fifth case, there had been an old suppurative otitis, but the arthritic symptoms had been manifested for two months before evidence of a sinus thrombosis.. In the second case three months passed before striking evidence of a sinus thrombosis appeared, the clinical picture having been entirely dominated by the joint swellings and the inflammation of serous surfaces. In the fourth case aspiration of the joint failed to recover bacteria. This experience in other cases led to the conclusion that it was unjustifiable to presuppose that pyogenic cocci were present in all secondary joint manifestations, otherwise abscesses of the joints would be observed much more frequently in general bacteriemic processes. Toxins could be designated as the cause of such bacteria-free joint exudations. Dr. Oppenheimer said that by no means was it contended as unlikely that after an acute middle ear infection symptoms of acute joint inflammation might not arise, which would then have to be considered as a symptom; but if after an acute otitis or during the course of a chronic suppurative otitis, acute arthritic symptoms were present, they must not be considered as primary, but as secondary metastatic complications resulting from an infective otitic phlebitis and an associated general bacteriemia. It did not seem amiss in view of the facts presented to suggest that the general practitioner should bear in mind in all cases of arthritic inflammation with associated otitic lesion that it was wise to consider the latter as the primary causative factor.

Dr. JOHN ROGERS, in opening the discussion, said that there were a great many of the acute and subacute non-suppurative inflammations of the joints that were bacterial in origin. A clear distinction should be made between the suppurative and the non-suppurative cases, both metastatic conditions which might complicate otitis media. The suppurative cases should be treated radically. The non-suppurative cases were the ones that gave the most difficulty because the diagnosis was not always easy. The gouty joint was not easy to differentiate from the metastatic joint complicating an otitis media which did not go on to suppuration. In cases of chronic rheumatoid arthritis there was often the doubt whether they were solely bacterial in origin, metabolic, or both. Dr. Rogers referred to one class of cases of subacute inflammation of the joint, or joints, in which invasion of the heart by bacteria occurred. With regard to the treatment of these metastatic mild rheumatic, so-called, infections, bacterial in origin, the surgical treatment was, in his opinion, always useful. It was not necessary in all these cases to incise and drain, but the institution of such mild treatment as immobilization by plaster splints or strips was of great value and productive of the best results. The treatment by vaccines had always appealed to him as a very useful way of improving these cases. In these conditions there were several kinds of bacteria involved and it was by no means easy to state which micro-organism was the cause of the trouble. With a chronic infection of the ear and with metastatic foci elsewhere it could be well assumed that these foci developed from the ear process. It was sometimes very difficult to determine what bacteria could be used in the preparation of a vaccine in these cases and he said that he had been disappointed in the results that he had obtained, but what results he had had offered hope for the future.

Dr. WELLS P. EAGLETON of Newark, N. J., said that he had seen personally but one case of a metastatic condition complicating suppurative otitis media and the symptoms of the involved joint overshadowed those of the ear. There was no doubt in this case of the primary source of infection. There might have been many cases he had seen perhaps which really originated from the ear. With regard to a statement made in relation to a general pyemic infection in which it was said that the cerebral condition was the result of invasion by direct continuity, Dr. Eagleton said that he had seen one case in which an embolism circulated in the blood and at last found lodgment in the brain, but this was not due to any direct continuity of tissues. With regard to what they should do in cases of a general involvement, this was what interested him very much. Many years ago he met with what might be called an unfortunate experience. Following a sinus thrombosis operation the patient complained of pain in the nose. The thrombosis was discovered and operation was performed and the thrombosis turned out. The pain was very severe and the temperature was high. Four days after an orthopedist was called in consultation and it was shown that the hip joint was involved and an extension apparatus was placed on the patient. One week following it was found that this hip was spontaneously dislocated. An abscess formed which was evacuated. One week later the other hip became dislocated, an abscess formed and this too was evacuated. In this case there were two primarily damaged hips. In these cases of general involvement of the joints, whether there was fluctuation or not, he advised aspiration of the joint and a bacterial investigation of the fluid. If, after aspiration of a joint, after smears had been made and examined and pyogenic organisms had been proven to be present, the joint should be opened, irrigated, and then closed. This procedure was uniformly successful in caring for the infection but always in effecting a complete restoration of function. On the other hand, many cases would recover after immobilization of the joint if there were no bacteria in the joint. There was great danger in delay in these cases. Dr. Eagleton believed that these joints should always be aspirated in order to determine whether any bacteria were present or not.

Dr. L. A. LA FETRA said that during the period from January 1, 1913, to November 15, 1914, there were treated in the children's wards of Bellevue Hospital 177 cases of otitis media. Of these 132 were acute; the treatment consisted of single paracentesis in 36 cases and double paracentesis in 66. There was spontaneous opening, frequently before the patient entered the hospital, in 28 instances. The opening was double in 10 of these and single in 18. In eight cases there was no opening and no paracentesis was done. Among these 132 cases of acute otitis the complications were as follows: Acute colitis, one case; post-auricular adenitis, one case; pneumonia, ten cases; serous meningitis, one case; septicemia with pericarditis and pleuritis, one case. In the case of serous meningitis the blood culture was negative throughout and the cells in the spinal fluid numbered on the fourth day 480; on the fifth day 262; on the seventh day 20, and on the eighth day 37. The infant made a complete recovery. In the case of septicemia with pericarditis and pleuritis there was acute purulent otitis media involving both ears. The infant was seven months of age and died of general poisoning, the termination having been due to a hemorrhagic infarct in the right lung. It was to be noted that there was not a single instance of mastoid disease developing in these 132 cases. The speaker said his experience in private practice had led him to feel that with early and perhaps frequent opening of the drum membrane, mastoid complications in infants and young children should be exceedingly infrequent. During the past fifteen years he had had arise in his private practice only five cases of mastoid complication. He had had no experience either in the hospital or in private practice with the complication of sinus thrombosis, and the hospital case of general septicemia mentioned was the only one he had seen. During the same period there were 45 cases of chronic otitis media. Double paracentesis was done in one of them and single in three. In one instance there was no opening and no paracentesis was done, while in 38 cases there was spontaneous opening before entering the hospital, double in 22 and single in 16. Among these 45 chronic cases, there was one instance of mastoiditis and one of temporal venoidal abscess with no mastoid involvement. Among the whole number of acute and chronic cases there was not a single instance of rheumatism or septic joints. It seemed to him that it would be of interest to add in this discussion the number of cases of rheumatic fever and of sepsis treated in the hospital during the same period. During the year 1913-14 there were 33 cases of rheumatic fever. In one case there were trifling ear symptoms which soon subsided. This patient had a hemolytic streptococcus in his blood, but at the

time of discharge this organism had disappeared and both ear drums were normal. During the same period there were treated in the wards 33 cases of valvular heart disease, some of which were acute, but most of which were chronic. In none of these was there any symptom or sign referable to the ear. There were 10 cases of septicemia during the same period. Of these one infant of four months had acute purulent otitis on the right side and one infant, 18 days old, had a double otitis with meningitis, a part of a general septicemia. Altogether then there were among the 177 cases of otitis, one case of septicemia, none of joint involvement. Among the 33 rheumatic cases there was only one of mild otitis; among 10 cases of septicemia, there were two with otitis.

Dr. J. H. GÜNTZER reported the case of a girl, eight years of age, who had had her tonsils and adenoids removed two years ago. Because of frequent colds, the family physician had advised the removal of the remaining adenoid tissue. This was done on April 27, 1914. On May 6 the speaker saw the patient complaining of earache. There was slight mastoid tenderness and a myringotomy was done. There was a free discharge for a few days. On May 11, the tenderness increased and a mastoidectomy was performed. The culture showed staphylococcus. The mastoid was filled with granulations and zygomatic cells well developed. On May 17 pus was evacuated from the zygomatic region, following which there was fluctuating temperature for three days, when clinical manifestations of sinus thrombosis were noted. A jugular resection was then done. On May 20 there was no abatement of the septic temperature and the jugular bulb was exposed and pus evacuated from this region. The temperature had distinct evening rise for about two weeks before a swelling of the right ankle joint appeared, with fluctuation. This joint was drained. On June 14, Dr. John Hartwell excised the astragalus which was necrosed. The joint was thoroughly drained. On turning the child over a bulging was found in the right scapular region which was opened and pus evacuated; exploration revealed necrosis of the bone. On June 21, pus was evacuated from the right hip joint. On July 11, pus was evacuated from behind the right hip. On July 15, the right femur was opened and pus evacuated from the medullary canal. On August 12 there was a second opening and evacuation of pus from the right femur below and behind. The general condition varied during all this time. The child had no chills, never vomited, and had no cerebral symptoms. She had paralysis of the external rectus muscle of the left eye which entirely cleared up in about three weeks. During these five months necrosis of the skin occurred wherever there was bodily contact. The occiput was exposed, every spinous process of the vertebræ, the crest of the pelvic bones, the posterior aspect of nearly all the ribs, the heels, and the contact surfaces of both legs. The urine later showed albumin and casts; various blood counts showed leucocytosis and increased polymorphonuclears. Warm days in the early part of September caused watery diarrhea from which the patient never rallied, which was either toxic or compensatory for the poor kidney action. These were the worst toxic cases that could fall to one's lot.

Dr. GODFREY R. PISEK agreed that they did meet with cases of arthritic involvement which followed a pus focus somewhere and undoubtedly could have joint involvement from a suppurative otitis media. He did not like the term "rheumatism" as it had been applied. In the minds of many practitioners there still existed the old idea that scarlet fever might be followed by a "rheumatic" attack. In this disease they did meet with cases of arthritis, usually multiple in form, but rarely did they go on to joint suppuration. He hoped that light would soon be thrown upon these non-suppurative arthritides. In young children we occasionally see a pneumococcic arthritis. These are supposed to be primary, since no focus can be found elsewhere. Probably there is a hidden focus perhaps related to such conditions as described by the reader of the paper. A number of cases of otitis and arthritis had occurred at the Willard Parker Hospital. Among 934 cases of diphtheria, 83 or approximately 8.8 per cent. had an otitis media and there were among these no cases of arthritis that developed. In the scarlet fever division, 1,079 cases, 223 developed an otitis, 30 coming to mastoid operation. Taking the cases of certain infectious diseases, such as scarlet fever, diphtheria, measles, etc., there were during the last and up to the present time of this year, 6,408 cases; among these there were 677 cases of otitis media, *i.e.* about 10½ per cent. There were 128 cases of arthritis, or about 2 per cent. It was shown that suppurative arthritis was uncommon. In the treatment of these cases immobilization was usually sufficient. The salicylates if given at all should be given purely for their analgesic effect. Sinus thrombosis was uncommon in early life.

Dr. JAMES F. MCKERNON said that these metastatic abscesses did occur and much more frequently than was formerly supposed. They often saw cases of septic sinus thrombosis and wondered why they did not occur more frequently, and it struck him that some explanation might be given, such as the virulence and activity of the organism producing the trouble and, of course, the resistance of the patient. These cases developed later in life, and to him it was strange that they did not develop earlier. He recalled one case of a metastatis following a suppurative otitis media which had practically cleared up. Some time later the hip was examined and found to be practically ankylosed and there was present a large amount of swelling. An abscess had formed which had opened and drained. Dr. McKernon said that he was inclined to side with the views taken by Dr. Eagleton in regard to these joint conditions—in every joint abscess following a septic sinus thrombosis one should examine carefully to find the specific microorganism that was present and causing the trouble.

Dr. REGINALD H. SAYRE said that he had seen instances of arthritis involving the cerebral vertebra which followed the mastoid operation. These cases, which usually involved the first and second cervical vertebræ were sometimes mistaken for torticollis. Undoubtedly an infection of the first, second, or third cervical vertebra from a metastaic process from the middle ear which was suppurating was as common as from a suppurating tonsillitis.

Dr. LEO B. MEYER said that Dr. Oppenheimer reported five cases of suppurative arthritis in which the primary focus, the ear, was so mild as to be discovered only on careful search, and referred to eight other cases in which the ear as primary focus was very evident. In all these cases a sinus thrombosis existed. It was generally understood that where general infection with bacteriemia occurred, following an otitis media, a sinus thrombosis must exist. In fact bacteriemia occurring in the course of an otitis media meant sinus thrombosis. That, however, general infection could occur following an otitis media without sinus thrombosis being present was not generally known; in fact was doubted by many, though Libman, to whom they were indebted for most of the knowledge on this subject, mentioned the possibility, especially where children were concerned. Dr. Oppenheimer would remember a case he presented last year at another medical society, and which he discussed, where exactlv this condition was present. It was the case of an infant, sixteen weeks old, that was operated upon by him for a suppurative arthritis of knee (incision of joint, irrigation with 2 per cent. formalin in glycerin, and complete closure of joint) following suppurative otitis media without any evidence of either mastoiditis or sinus thrombosis. The child, on whom he had to operate subsequently for several other metastatic infections, made a complete recovery, with normal knee-joint function. That this child might have had an unrecognized mastoiditis and sinus thrombosis was not impossible, but if it did it recovered without beng operated upon for it.

Dr. M. D. LEDERMAN recalled the history of the patient he had shown before the Otological Section about a year ago. A female child, seven years of age, was admitted to his service at Lebanon Hospital for mastoid and sinus complications following an acute purulent otitis media of severe character. A week after the mastoid and sinus operation, during which a parietal thrombus was found and removed, characteristic symptoms appeared which demanded prompt resection of the internal jugular vein, though physical signs of the chest showed the presence of a pneumonic involvement of the right side, posteriorly at this time. Two severe chills, with typical septic temperature and sweating, indicated prompt intervention in spite of the existing pneumonia. Two inches of the internal jugular vein were resected, and in cutting through the vein near the clavicle a white thrombus was seen. No further chills were noted after this operation, and the fever gradually subsided for a few days as the pneumonia improved. A week later the temperature jumped to 105°, when pain and tenderness in the region of both ankle joints appeared. Every movement of the feet caused much suffering. Both areas were incised and considerable pus

was found. Bacteriological examination showed streptococcus infection similar in character to that found in the mastoid disease. Another abscess of the left foot developed and was opened. Severe pain and tenderness in the right thigh also followed, but under wet dressing this invasion cleared without suppuration. Another collection of pus was evacuated in the left foot. In the meantime the mastoid and neck wounds had healed, but the ankle abscess required further treatment. The joints proper were not involved. For fully a month after her discharge from the hospital the little girl was confined to her room, with an irregular temperature touching 105°. After she was able to get out of bed it was two weeks before she could walk properly. During her stay at the hospital she received a number of streptococcic vaccine injections. Another case, which the speaker showed before this section a few years ago, which belongs to this group of complications, was that of a young girl, fifteen years of age, who developed a pulmonary abscess, cervical infection, and alveolar infection following a chronic suppuration of the middle ear, with mastoid sinus and internal jugular involvement. The clinical history in this instance at first suggested a typhoid infection, as no subjective aural symptoms were offered. The girl came to the Lebanon Hospital with high temperature, pain in the right iliac region, and on general examination was found to be about three months pregnant. Following the mastoid and jugular operation the patient aborted at the third day. At about the fifth day pulmonary symptoms appeared, and a day later more purulent expectoration was observed with the frequent paroxysms of cough. The secretion from the chest was foul smelling and soon assumed a distinct purulent character. The bacteriological examination showed streptococcus infection. About four or five weeks later the chest was aspirated posteriorly, as the temperature persisted, but no pus was found in the pleural cavity. Gradually the lungs cleared and the purulent expectoration lessened. Severe toothache appeared and an alveolar abscess was discovered and incised. The patient was discharged from the hospital about two months, following the mastoid and jugular operations, in good general condition. The ear discharge was still active, but ceased under local treatment in about six weeks. Both these cases were instances of severe metastatic infections following purulent disease of the middle ear, and their ultimate recovery was indeed very fortunate.

Election of Officers.—*President*, Dr. Walter E. James; *Vice-President*, Dr. Edward D. Fisher; *Corresponding Secretary*, Dr. D. Bryson Delavan; *Treasurer*, Dr. Reginald H. Sayre; *Trustee*, Dr. Wisner R. Townsend; *Member of Committee on Library*, Dr. Lewis F. Frissell; *Members of Committee on Admissions*, Dr. N. R. Norton (5 years); Dr. W. L. Stowell (3 years); Dr. W. L. Niles (1 year)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEW YORK STATE BOARD OF MEDICAL EXAMINERS.

May, 1914.

ANATOMY.

Answer a total of 10 of the questions on this paper but no more.

Candidates must answer each of the first six questions.

1. Describe the head of (*a*) the radius, (*b*) the ulna, (*c*) the femur, (*d*) the humerus.
2. Name the ligaments of the knee joint and describe one of them.
3. Describe the sinuses of the dura mater.
4. Describe the minute anatomy of the pancreas.
5. Give the position and the relations of the kidney.
6. Name the important structures at the base of the brain.
7. Give the course of the aorta and the names of its branches.
8. Give the origin, insertion, and nerve supply of the latissimus dorsi muscle.
9. Give the boundaries of the left lung and the liver in relation to the surface of the body.
10. Describe the broad ligament of the uterus and give the position and the relations of the structures contained therein.
11. Describe the internal semilunar fibrocartilage (*Meniscus medialis*) and the triangular fibrocartilage (*Discus articularis*).
12. Describe the differences between the male pelvis and the female pelvis.

PHYSIOLOGY.

Answer a total of 10 of the questions on this paper but no more.

Candidates must answer each of the first six questions.

1. Describe in detail the functions of the cardiac centers of the medulla.
2. Describe the normal condition of skeletal muscles as regards elastic tension and its effect on the contractility.
3. Describe in detail the action of the muscularis in the small intestine.
4. Describe in detail the chemical changes taking place in the blood during respiration.
5. In a well balanced diet what is the average proportion of (*a*) proteids, (*b*) fats, (*c*) carbohydrates? How many calories would be derived from such a diet?
6. Describe the paralysis resulting from a destructive lesion that involves the posterior limb of the internal capsule (capsula interna) of the brain.
7. What is the active principle of the internal secretion of adrenals? What is its function?
8. Describe the causes of secretion by the pancreas.
9. How are the dissipation and the conservation of heat controlled?
10. What is the function of the Eustachian tube?
11. Describe in detail the coagulation of the blood.
12. Give three examples of enzymes and state the specific function of each.

ANSWERS.

May, 1914.

ANATOMY.

1. The *head of the radius* articulates with the capitellum of the humerus and with the lesser sigmoid cavity of the ulna; it is surrounded by the orbicular ligament; immediately below it is a constricted portion called the neck, and below this is the bicipital tuberosity for the insertion of the tendon of the biceps.

The *head of the ulna* is situated at the lower extremity of that bone and articulates with the interarticular fibrocartilage which separates it from the wrist-joint; it also articulates with the sigmoid cavity of the radius.

The *head of the femur* is globular, with an ovoid depression near the center for the attachment of the ligamentum teres; it is received into the acetabulum to form the hip-joint.

The *head of the humerus* is nearly hemispherical, and articulates with the glenoid cavity of the scapula; it is slightly constricted at the anatomical neck.

2. The *ligaments of the knee-joint* are divided into two sets, the external and internal ligaments. The external ligaments are the anterior, posterior, internal lateral, two external laterals, and capsular; the internal ligaments are the anterior or external crucial, posterior or internal crucial, two semilunar, transverse, coronary, ligamentum mucosum, and ligamenta alaria.

The *posterior ligament* is attached above to the upper margin of the intercondyloid notch of the femur, and below to the posterior margin of the head of the tibia. Attached to it is the posterior ligament of Winslow, which is an expansion from the semimembranosus muscle. The posterior ligament forms part of the floor of the popliteal space, and the popliteal artery rests upon it.

3. SINUSES OF THE DURA. There are seventeen of them. "*Superior longitudinal sinus:* begins at crista galli, where it may communicate through foramen cecum with nasal veins, runs back in upper border of falx cerebri to torcular Herophili, usually joining right lateral sinus; receives superior cerebral, parietal, and emissary veins. Intersected by fibrous bands, the chordæ Willisii; the lumen is triangular, and on either side lie the Pacchionian bodies.

Inferior longitudinal: along posterior ⅔ of free margin of falx cerebri to straight sinus.

Tentorial or *straight:* is placed at junction of tentorium and falx cerebri, goes to torcular Herophili, ending usually in left lateral sinus; receives inferior longitudinal sinus, venæ Galeni, inferior median cerebral, and superior cerebellar veins.

Lateral (2): from torcular Herophili to foramen lacerum posterius, goes into internal jugular vein, receives superior longitudinal, superior petrosal, straight and occipital sinuses, and mastoid vein. Join inferior petrosal sinus to form internal jugular vein below jugular foramen.

Occipital (2): smallest; from posterior margin of foramen magnum to torcular Herophili.

Cavernous (2): by side of sella Turcica, passes from sphenoidal fissure to apex of petrous part of temporal. Receives ophthalmic veins which connect the angular vein with this sinus; also inferior anterior cerebral veins and sinus alæ parvæ.

Circular: surrounds pituitary body, connects the cavernous sinuses.

Inferior petrosal (2): from termination of cavernous to internal jugular vein above petrooccipital suture.

Transverse: connects the interior petrosal sinuses across basilar process of occipital bone.

Superior petrosal (2): placed on superior border of petrous part of temporal, connecting lateral and cavernous sinuses; receives inferior lateral cerebral, and anterior lateral cerebellar veins.

Sinus alæ parvæ (*sphenoparictal*) receives some meningeal and inferior cerebral veins, and runs inwards along free margin of lesser wing of sphenoid to cavernous sinus."—(*Aids to Anatomy.*)

4. "The *pancreas* consists for the most part of long tubular acini of columnar or polygonal epithelial cells, supported by very loose fibrous tissue. The cells are of the serum-secreting type. Their inner portion shows granules; the outer part is clearer, and sometimes striped. The pancreas has, therefore, a general resemblance to the parotid gland, but differs from it in two respects: (1) The intralobular ducts are lined by flat epithelium, and are inconspicuous; (2) between the acini here and there are islands of epithelial cells without any glandular arrangement. These are the *islets of Langerhans*. In some of the acini, close to the lumen, stellate cells can be seen. These are the *centro-acinar cells of Langerhans*, and are probably continued into the acini from the small ducts. There are spaces between the cells continuous with the lumen of the acini. The larger ducts are lined with columnar epithelium, with a few goblet cells here and there, and the largest ducts have a ring of non-striped muscles in the fibrous wall. Numerous nerve fibers with nerve cells in their course run through the pancreas and end among the cells. Some of them may terminate in Pacinian corpuscles."—(*Aids to Histology.*)

5. The kidneys are situated for the most part in the hypochondriac and epigastric regions of the abdomen behind the peritoneum, extending from the eleventh rib to within an inch of the crista ilii, the right being placed lower than the left, and lying slightly in the right lumbar and umbilical regions.

Relations.—The relations of the two kidneys differ somewhat; each is placed so that its anterior surface looks outward and the posterior inward, the upper end being nearer the mid-line than the lower. Each kidney is covered partly on its anterior surface by peritoneum.

Relations of the right kidney. In front: Right lobe of liver, second part of duodenum, hepatic flexure of colon (of which the last two areas are nonperitoneal). *Behind:* Diaphragm, quadratus lumborum, psoas, fasciæ covering these muscles, anterior lamella of lumbar aponeurosis, iliohypogastric, ilioinguinal nerves, last dorsal; first lumbar artery, pleura, last intercostal space and twelfth rib.

Relations of the left kidney. In front: Fundus of stomach, posterointernal surface of spleen, tail of pancreas, descending colon (of which last two are nonperitoneal. *Behind:* As on right, except that left kidney, lying rather higher, lies over eleventh rib.

Above each kidney is the suprarenal body.

Below each kidney is the iliac crest.—(*Aids to Anatomy.*)

6. *Important structures at the base of the brain:* Corpus callosum, lamina cinerea, optic commissure, tuber cinereum, infundibulum, anterior and posterior perforated spaces, olfactory bulbs, optic tracts, fissure of Sylvius, crura cerebri, pituitary body, corpora albicantia, pons Varolii, medulla, and superficial origins of the cranial nerves.

7. The *aorta* commences at the upper part of the left ventricle and, after ascending for a short distance, arches backward and to the left over the root of the left lung, then descends on the left side of the vertebral column, passes through the aortic opening in the diaphragm, and terminates opposite the lower border of the fourth lumbar vertebra where it bifurcates into the right and left common iliac arteries. *Branches:* Coronary arteries, innominate, left common carotid, left subclavian, bronchial, esophageal, pericardial, posterior mediastinal, intercostal, phrenic, celiac axis, superior mesenteric, suprarenal, renal, spermatic (or ovarian), inferior mesenteric, lumbar, and sacra media.

8. LATISSIMUS DORSI. *Origin:* Spinous processes of lower six dorsal vertebræ and posterior layer of lumbar fascia, from external lip of crest of ilium, from three or four lower ribs. *Insertion:* Bicipital groove of humerus. *Nerve supply:* Long subscapular nerve.

9. The *left lung.* The apex is about one and a half inches above the left clavicle, as it descends it approaches the right lung, till they nearly meet in the median line at the level of the second costal cartilage. From here it goes vertically down to about the level of the fourth costal cartilage. Here it curves outward and downward to reach the seventh rib in the midaxillary line, the ninth rib in the midscapular line, and the eleventh rib at the vertebral column.

The *liver:* "Its upper edge reaches as high as the fourth interspace or fifth rib in the right mammary line, and in the left mammary line to the fifth space or sixth rib. It crosses the sternum at the sternoxiphoid junction. Its lower border on the right side in the mammary line corresponds to the margin of the ribs, about a half inch lower in women. Posteriorly it corresponds to the tenth and eleventh ribs and the lower end of the eleventh dorsal vertebra behind. In the epigastrium it passes from the tip of the ninth costal cartilage on the right side to that of the eighth on the left side. In the median line it is about midway between the sternoxiphoid articulation and the umbilicus."—(Thomas' *Surgical Anatomy.*)

10. THE BROAD LIGAMENTS OF THE UTERUS. "Duplicature of peritoneum, extending transversely from sides of uterus and vagina outward to sides of pelvic wall—the two layers being continuous superiorly at their free border—and diverging laterally and inferiorly to envelop various structures. *Relations.—Superior or free border* (mesosalpinx): summit of duplicature, where it envelops Fallopian tube. Extends from side of uterus toward pelvic wall, to beyond the fimbriated extremity of Fallopian tube. Infundibulo-pelvic ligament—that portion of superior border of broad ligament between fimbriated extremity of Fallopian tube and lower attachment of broad ligament—a concave, rounded border—the ovarian vessels being conveyed in this ligament. *Inferior border:* attached to levator ani muscle and rectovesical fascia. Ureters, vessels, and nerves pass through the subperitoneal areolar tissue between its layers. *Internal border:* attached to lateral walls of uterus and vagina. Uterovaginal vessels and muscular bands pass between the two laminæ. *External border:* In contact with obturator fascia. Transmits uterine vessels and round ligament. *Structures between two layers of broad ligament.* Ovary projects from posterior lamina. Ligament of ovary—from angle of uterus to lower or internal aspect of ovary. Fallopian tube—in upper free margin. Round ligament forms a ridge beneath anterior lamina, on its way to inguinal canal. Parovarium (fetal relic)—between ovary and outer part Fallopian tube. Duct of Gaertner; hydatid of Morgagni; small cysts—all fetal relics. Uterine, ovarian, and funicular vessels; lymphatics; and uterine plexus of nerves. Subperitoneal fatty areolar tissue. Involuntary muscular fibers—from obturator fascia to sides of uterus and vagina."—(Bickham's *Operative Surgery.*)

11. "*The internal semilunar fibrocartilage* (*meniscus medialis*) is nearly semicircular in form, a little elongated from before backward, and broader behind than in front; its anterior extremity, thin and pointed, is attached to a depression on the anterior margin of the head of the tibia, in front of the anterior crucial ligament; its posterior extremity is attached to the depression behind the spine, between the attachments of the external semilunar fibrocartilage and the posterior crucial ligaments."

"*The triangular interarticular fibrocartilage* (*discus articularis*) is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower end of this bone and the radius firmly together. Its periphery is thicker than its center, which is thin and occasionally perforated. It is attached by its apex to a depression which separates the styloid process of the ulna from the head of that bone, and by its base, which is thin, to the prominent edge of the radius, which separates the sigmoid cavity from the carpal articulating

surface. Its margins are united to the ligaments of the wrist-joint. Its upper surface, smooth and concave, articulates with the head of the ulna, forming an arthrodial joint; its under surface, also concave and smooth, forms part of the wrist-joint and articulates with the cuneiform and inner part of the semilunar bone. Both surfaces are lined by a synovial membrane—the upper surface, by one peculiar to the radioulnar articulation; the under surface by the synovial membrane of the wrist."—(Gray's *Anatomy.*)

12. The chief differences between the male and female pelvis are thus tabulated in Morris' *Anatomy:*

MALE.	FEMALE.
Bones heavier and rougher.	Bones more slender.
Ilia less vertical.	Ilia more vertical.
Iliac fossæ deeper.	Iliac fossæ shallower.
False pelvis relatively wider.	False pelvis relatively narrower.
True pelvis deeper.	True pelvis shallower.
True pelvis narrower.	True pelvis wider.
Inlet more heart-shaped.	Inlet more oval.
Symphysis deeper.	Symphysis shallower.
Tuberosities of ischia inflexed.	Tuberosities of ischia everted.
Pubic arch narrower and more pointed.	Pubic arch wider and more rounded.
Margins of ischiopubic rami more everted.	Margins of ischiopubic rami less everted.
Obturator foramen oval.	Obturator foramen triangular.
Sacrum narrower and more curved.	Sacrum wider and less curved.
Capacity of true pelvis less.	Capacity of true pelvis greater.

PHYSIOLOGY.

1. The *cardiac centers in the medulla.* The *cardio-inhibitory* center is connected with the nucleus of the vagus in the floor of the fourth ventricle, and the fibers from it pass to the heart along the vagus nerve. Its function is to slow the beat of the heart. It is sometimes known as the anabolic center, because it lessens the rate and force of the heart and so allows time for building-up processes (anabolism). If the peripheral end of the cut vagus is stimulated, the heart is slowed and may be entirely stopped. It is a tonically active center, that is, it acts continuously, so that the simple cutting of the vagus takes off the brake and lets the heart run away.

The *cardio-accelerator* center is also in the floor of the fourth ventricle. It acts through the sympathetic fibers which descend in the spinal cord and leave it through the anterior roots of the first and second dorsal nerves, and go thence to the cardiac plexus. This center keeps up the rate of the heart beat.

These centers may be stimulated by apparent impulses, such as *psychic* from the cortex cerebri, or *cutaneous*, or *visceral.* The centers are also affected by the state of the blood; thus excess of carbon dioxide in the blood, as in the beginning of asphyxia, stimulates the cardiac centers and makes the heart beat more strongly and more rapidly. Increased temperature of the blood also increases the rapidity of the heart's action.

2. The *elasticity of muscle* is small in amount but is perfect in quality; it cannot be stretched to any great extent without the fibers being damaged, but it returns completely to its original condition. Skeletal muscle is always in a state of tonus. This condition is kept up by the nervous system, and the impulses start from the muscle tonus centers in the spinal cord. Any interference with the reflex arc destroys the tonus or lessens it (hypotonus). This reflex arc consists of (1) afferent fibers to the spinal ganglia on the posterior roots of spinal nerve; (2) fibers to the cells of the posterior cornu; (3) an intraspinal neuron between the cells of the posterior cornu cells and the cells of the anterior cornu; and (4) an efferent neuron cell in the anterior cornu and axis cylinder to the muscle.

The *effect on contractility* is that the muscle is braced up, always ready for action; there is no "slack" to be taken in; contraction can therefore begin at once, and the latent period is shortened.

3. The unstriped muscle of the small intestine acts in two ways. (1) There are the *peristaltic movements* from the duodenum to the ileum. When food is being passed along the intestine, peristalsis consists in the inhibition of muscle in front of the food, and contraction of the muscle behind it; this process is repeated again and again, and food is forced along by its means. Peristalsis, in normal circumstances, acts in one way only, namely downwards. If a piece of intestine is resected, and turned round and sewed into place so that the top end takes the place formerly occupied by the lower end and *vice versa*, peristalsis in this piece still occurs in the originally normal way, and the food is found congregated at the top end. This proves a neurogenic origin for the movement; it occurs through Auerbach's plexus. The rate of this peristalsis is said to be about one inch per minute. (2) There are also *rhythmic segmental movements.* These are caused by the circular muscular fibers alone, contracting in one place and relaxing in another, and puckering and bulging irregularly, so that the contents of the intestine are mixed together thoroughly. This movement may proceed either upwards or downwards, and is myogenic in origin.

4. *Chemical changes in the blood in respiration.* Venous blood is brought to the lungs for aeration (external respiration); after aeration it is carried to the tissues, where internal respiration occurs.

External respiration. Between the air in the alveoli of the lungs and the blood there exists the endothelium of the capillaries and the epithelium of the walls of the acini. Through these two layers the interchanges between the air and the blood must take place. Inspired air contains 21 per cent. of oxygen; expired air contains 16 per cent. of oxygen; therefore 5 per cent. of oxygen is absorbed. The oxygen tension in venous blood as it reaches the lung is low, and so by diffusion of gases oxygen passes from the air in the alveoli to the blood until an equilibrium of tension is reached. But it is found that the oxygen tension of arterial blood is above that of air, and this extra amount of oxygen is taken into the blood by the selective power of the epithelium lining the acini of the lungs. The oxygen is then combined loosely with the hemoglobin of the blood, forming oxyhemoglobin. The oxygen is combined with the hematin part of the hemoglobin, and the amount absorbed depends on the amount of iron in the hematin (usually about 0.4 per cent.). The oxyhemoglobin is carried by the blood to the tissues. The amount of carbon dioxide in inspired air is 0.04 per cent.; in expired air it is 4.4 per cent.; so that, roughly, about 4 per cent. of carbon dioxide is expired. The carbon dioxide tension in venous blood is high; in alveolar air it is low; and so by diffusion carbon dioxide leaves the blood and passes into the alveolar air until equilibrium is reached and the carbon dioxide is prevented from returning into arterial blood again by the selective action (or biotic activity) of the epithelium lining the acini. The nitrogen of the air is only a diluent, and does not enter into any chemical action. One hundred volumes of blood yield about sixty volumes of gas:

	VOLS. OF OXYGEN	VOLS. OF CARBON DIOXIDE
100 Vols. of arterial blood	20	40
100 Vols. of venous blood	12	48

Internal respiration. Arterial blood leaves the lungs and is carried to the tissues, where the oxygen from the oxyhemoglobin is absorbed by the molecules of proteins, fats and carbohydrates in the tissues; oxidation does not occur immediately, but eventually it does. Some of the oxygen is used to form water, which passes into the blood and is excreted by the kidneys, skin and lungs; but most of the oxygen goes to form carbon dioxide, and this passes back into the venous capillaries. This oxidation is aided by tissue enzymes called oxidases. The carbon dioxide returns to the lungs by the venous blood, in various ways: absorbed to the protein molecules, as Na_2CO_3 and $NaHCO_3$, and a small amount is free in the blood.

5. Ranke's diet calls for:

Proteins .....100 grams
Fats .....100 grams } per diem
Carbohydrates .....250 grams

One gram of protein represents 4.1 calories.
One gram of fat represents 9.3 calories.
One gram of carbohydrate represents 4.1 calories.
The above diet, therefore, yields:

Proteid ..... 410 calories
Fats ..... 930 calories } Total, 2365 calories
Carbohydrates .....1025 calories

6. *Internal Capsule.*—"In the comparatively con-

stricted region of the internal capsule practically all of the motor and sensory projection fibers of the cerebral cortex are closely packed together. The internal capsule is made up of a so-called knee; an anterior, lenticulo-caudate (lenticulo-striate) limb; and a posterior limb, of which the anterior two-thirds is called the lenticulo-optic (lenticulo-thalamic) segment, and the posterior one-third the retrolenticular segment. A lesion of the knee gives rise to disturbances of the motor nerves of the eye, the motor part of the trigeminus, the facial, and the hypoglossal; in consequence; in addition to the obvious paralyses, disorders of articulation ensue, and if the lesion be on the left side aphasia. A lesion just posterior to the knee (the pyramidal tract), implicating in order the neurons for the face, arm, and leg, causes usually hemiplegia of the opposite half of the body; monoplegia is very rare, the lesion scarcely ever being small enough to involve only the neurons innervating one limb. A lesion of the posterior third (the retrolenticular segment) of the posterior limb of the internal capsule (which transmits sensory fibers for the entire body, as well as the optic and auditory neurons) gives rise to hemianesthesia (and related sensory changes) of the opposite half of the body, homonymous hemianopsia, and deafness on the opposite side. In most cases, however, notably in cerebral hemorrhage (of which the internal capsule is the common seat), the results are usually varying combinations of those mentioned."—(Kelly's *Practice of Medicine.*)

7. The active principle of the suprarenal gland is adrenalin or suprarenin. Its function is to keep up the blood pressure by stimulation of the ends of the vasomotor nerves; an exception to this is the vasomotor nerve of the kidneys; its action here is to dilate the kidney arterioles and so produce diuresis. The secretion from the cortical portion of the gland helps to maintain general body strength and nutrition; it also has some influence on the growth and development of the body; it may also help to destroy toxins.

8. "According to the evidence at present in our possession we must believe that the pancreatic secretion, like the gastric secretion, consists of two parts: (1) A nervous secretion caused by the secretory fibers in the vagus and splanchnic; (2) a chemical secretion due to the action of the secretin. These two secretions are said to present quite different characters. The former is thick, opalescent, rich in ferments and proteins, but poor in alkalies. The trypsin contained in it may be secreted in active form, and the secretion is suspended by the action of atropine. Administration of pilocarpine, on the contrary, excites this secretion. The chemical secretion, on the contrary, is thin and watery, contains relatively little ferment or proteins, and is rich in alkali. The trypsin in it is secreted in inactive form, and the secretion is not affected by the administration of atropine."—(*Howell's Physiology.*)

9. The normal body temperature is *regulated* and *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested: (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Heat is given off from the body, by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

10. *Function of the Eustachian tube* is: (1) To maintain equilibrium between the atmospheric pressure in the middle ear and the outside air. (2) The ciliæ on the epithelium lining the tube filter the incoming air from the pharynx and so aid in keeping bacteria out of the middle ear. (3) It may act as a drainage tube for the middle ear. (4) It may possibly have some function as a resonating tube, as may be observed when it is closed in catarrhal conditions, when the voice sounds strange both to the patient and to others.

11. When blood is withdrawn from the blood-vessels of the living body it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts, forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear; and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats in the serum. The process is thus summed up by Halliburton. From the platelets, and to a lesser degree from the leucocytes, a material is shed out called *thrombogen;* from the formed elements of the blood, but also from the tissues over which the escaping blood flows, is shed out an activating agent, called *thrombokinase.* In the presence of *calcium* salts, thrombokinase activates thrombogen in such a way that an active enzyme is produced, which is called *thrombin.* In the blood plasma a protein substance exists, called *fibrinogen.* Thrombin acts on fibrinogen in such a way that it is transformed into the insoluble stringy material which is called *fibrin;* this entangles the corpuscles and forms the clot.

12.

THREE ENZYMES.	SPECIFIC FUNCTION.
Ptyalin.	To convert cooked starch into maltose.
Pepsin.	To split up proteins into proteoses and peptones, in an acid medium.
Trypsin.	To split up proteins into proteoses and peptones and other simpler bodies, in an alkaline medium.

(*To be continued.*)

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Suprarenal Extract and Infancy.—L. M. Spolverini has not been able to detect the presence of suprarenal extract in the blood of normal infants nor of those affected with a contagious disease. The administration of suprarenal extract to healthy infants gives rise to an increase in the amount of cholesterin in the blood and a diminution in the amount of urea in the cerebrospinal fluid. It also causes a slowing of the pulse and a rise in the blood pressure. These effects are not observed following the use of parathyroid extract.—*Il Policlinico.*

A UNIQUE CASE OF SYPHILIS OF THE CRANIUM AND SPINE;

WITH REMARKS ON SYPHILITIC BONE DYSTROPHY.

BY G. FRANK LYDSTON, M.D.,

CHICAGO.

FORMERLY PROFESSOR OF GENITOURINARY SURGERY AND SYPHILOLOGY, STATE UNIVERSITY OF ILLINOIS.

THE case herewith presented is the most interesting one of late syphilis that I ever have met with in my experience, and has so many novel and instructive features that I feel confident that it will prove interesting to the profession.

Man, aged fifty-six, American, came under my care August 27, 1913. He had been a farmer all his life until the past few years, since when he has lived in a country town. Married thirty-five years. Temperate. No history of trauma. Family history excellent. Wife and six children in perfect health. Wife, however, a few years since had an operation for uterine fibroids and for gallstones. Nothing in the history suggestive of syphilis in wife, children, or the patient himself could be elicited. Patient claims that he never had had extraconjugal sex relations, nor coitus prior to marriage, and that he was perfectly well until the previous October. Later, however, his wife asserted that he had been subject to spells of melancholy from time to time with moderate insomnia for about a year. There had been, so far as she could determine, no mental derangement nor headache during this time and no physical symptoms save "exhaustion."

In October, 1912, the patient began to suffer from pain in the right arm and shoulder. Later the pain shifted to the right ileocostal region. At the time he came under my observation there was marked pain in both ileocostal regions, most marked on the right side. There also had been severe pains in the lower limbs which, while still present, were no longer severe. The pains throughout the course of the case were described as "shooting" and "neuralgic." As the severity of the pains decreased, a generalized cutaneous hyperesthesia supervened, and there was marked "soreness and tenderness" in the lumbar region. In November, 1912, he began to lose flesh, and by the time he came under my observation he had reduced considerably in weight.

In December a course of six mercurial rubbings was taken at Hot Springs, evidently on general principles, as the patient went to the Springs seeking relief from what he supposed was "rheumatism." He also, at about this time, took a course of vigorous "osteopathic" treatment for his spine, the wisdom of which, in the light of subsequent events, may well be doubted.

Some ten weeks before I first saw the patient, he developed retention of urine. At about this time a small tumor appeared on the cranium, and exophthalmos of the left eye with almost total loss of vision developed. Digestion was impaired and there was marked constipation. The sexual function had remained normal up to the time the patient became considerably disabled.

On examination I found the following conditions: The prostate was moderately enlarged and somewhat tender, the enlargement being chiefly of the left lateral lobe. A small pedunculated polypus was found just within the anal sphincter. There were several hemorrhoids of moderate size. The bladder was distended with urine and regular catheterization had been found necessary. This retention was due to partial paralysis of the bladder and was in no way obstructive in origin. Cystoscopy showed a normal mucosa, vesical outlet and ureteral orifices.

There was considerable tenderness over all the spinal nerve roots. This was especially marked over the lower dorsal and upper lumbar nerves. The intercostal nerves corresponding to the former also were very tender, especially on the left side. Just at the right of the median line, alongside the dorsolumbar junction, was a rather vaguely defined, oblong, semielastic, insensitive tumor, measuring 4 x 6 cm.

In the median line of the cranium at the occipitoparietal junction—the superior occipital angle—was a slightly elastic, circumscribed tumor, the size of an English walnut. This was immovable and evidently was subperiosteal. At its base was a narrow ring of tissue which was bonelike to the touch, and suggestive of the osteophytic deposit that so often is found encircling a cephalhematoma. This previously had not been noticed.

The left eye presented exophthalmos in extreme degree and showed practically complete loss of vision.

There was no headache or mental disturbance—aside from slight hebetude—and no tenderness on pressure upon the cranium or the tumor above described. The reflexes were somewhat exaggerated. There were no evidences of muscular impairment save those presented by the bladder, the bowel, and the general muscular weakness incidental to the patient's exhausted condition. Heart and lungs normal.

A positive Wassermann had been obtained and antisyphilitic treatment instituted some weeks prior to his consulting me. A single intravenous salvarsan treatment had been given. No effect from treatment had been noted.

Temperature on admission was 98° F. Pulse 90.

August 27, 1913, under ether anesthesia, I made an exploratory incision in the cranial tumor. The tissue of the tumor presented the appearance of a typical gumma. The hard ring at its base proved to be due to extravasated blood with incipient osteophytic formation. There were no areas of softening in the tumor tissue proper, its consistency being that of a recently formed gumma. Subsequent microscopical examination of the tissue showed the usual characteristics of granuloma. Beneath the solid tissue of the tumor was an almost circular opening in the skull, at the junction of the parietal and occipital bones—the superior occipital angle—which readily admitted the index finger. The edges of the openings were rough and irregular. There was no pus or other fluid and no neoplasmic tissue between the cranium and the dura beneath the opening. The dura did not present any swelling and was apparently normal. The line of union of the parietal and occipital bones seemed slightly movable, suggesting that the disease of the bone involved the lines of osseous suture. With rongeur forceps I removed the surrounding bone until apparently normal bone was reached, the resulting circular opening being about 2 cm. in diameter. The wound was packed with finely powdered iodoform, two small iodoform gauze drains inserted and the whole covered with an iodoform gauze dressing.

There was no shock and the patient promptly recovered from the effects of the anesthesia.

Mercury was given by inunction in combination with increasing doses of iodide of potassium. Systematic catheterization of the bladder was necessary and while later a little improvement in the vesical condition was noted, the catheter and irrigations could at no time be dispensed with throughout the subsequent course of the case. There was at no time any evidence of renal involvement. The stomach proved rather intolerant and

it was necessary to intermit internal medication from time to time. Throughout the course of the case insomnia was a predominant feature. Considerable pain in the back was complained of. This did not seem to be localized in any particular area.

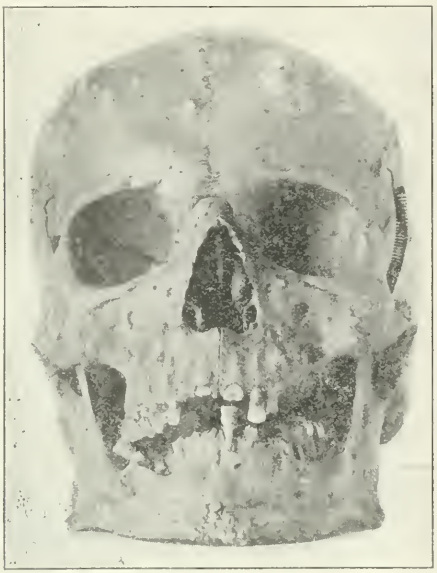

Fig. 1.

The exophthalmos rapidly subsided to a considerable degree immediately following the operation.

Dr. Harry S. Gradle saw the case in consultation on the fifth day after operation. His findings were as follows:

Left eye. About 3 mm. exophthalmos. Slight conjunctivitis. Motion limited slightly in extreme periphery. Cornea and anterior chamber normal. Pupil slightly more dilated than its fellow and slower to direct light reaction. Consensual reaction normal. Lens and vitreous clear. Nerve head slightly swollen (less than ½ mm.). No exudate present. Arteries thin, but nearly straight. Veins dilated and slightly tortuous. Retina around disc somewhat swollen. Fundus otherwise normal. Colors indefinite. No positive scotomata. Tension normal. Vision 2/70. (Papillitis. Remains of choked disc.)

Severe pains in the vesical region were complained of on the sixth day after operation. This pain decreased rapidly, however, and practically had disappeared within three or four days. The wound in the skull healed aseptically and was completely closed by the end of the second week after operation. During the progress of the case the patient was harassed by pain in the thighs, in the left especially.

On the fourteenth day salvarsan, 0.6 gm., was administered intramuscularly. This was repeated four weeks later. The indefinite tumor in the dorsolumbar region subsided rapidly and by the end of the second week was no longer perceptible.

The temperature ranged from 97.6° to normal for the first ten days after the operation. It then ranged from 98° to 100° for three or four days, when it again fell to a slightly subnormal average, and at no time rose above normal until the third day before death, when it was recorded as 100.2° per rectum, but shortly thereafter fell to 99° per rectum. Several hours before death the rectal temperature was 99.6°.

The pulse constantly ranged from 90 to 100 until a few days before death, when it rose rapidly to 120 and thereafter steadily increased until dissolution occurred.

The patient was affected from time to time by hysterical attacks and profound depression, but at no time showed any evidence of mental derangement while under my observation, save during periods of delirium at night. After the third week subsequent to the operation he was able to be dressed and sit in a reclining chair and even to move about the room and hospital halls a little. He expressed himself as feeling better when permitted to be up.

On September 25 the tumor at the dorsolumbar junction reappeared and developed quite rapidly. On October 3 I made an exploratory incision under cocaine. I found that the tumor was a hemocyst of considerable size, bilobed by the pressure of the supraspinous ligament, one lobe of the tumor resting on each side of the spine. The right side of the cyst was larger and extended for a distance of about 7 cm. alongside the spine beneath the deep fascia, which constituted its wall. Incision of the cyst freed probably three or more ounces of dark, perfectly fluid blood. The cavity of the cyst proved to be connected with the spinal canal by a necrotic opening about 15 mm. in diameter. The necrotic process involved a portion of the spinous processes and laminæ of the last dorsal and first lumbar vertebra. I removed with rongeur and curette the diseased bone and lightly packed the wound with iodoform gauze.

There was little venous oozing after the operation, but the postoperative course was favorable and healing was almost complete at the time of the patient's death.

The patient complained for some days of pain in the limbs, more insistently than before the operation. He suffered from pain in the upper limbs which previously had not been a prominent symptom. The pain gradually, however, became more endurable and thereafter remained of moderate severity.

Beginning Oct. 16, the patient became delirious at night. This symptom continued intermittently and with varying prominence until the termination of the case.

The cranial wound having healed perfectly, I had not examined the cranium for some days. Oct. 18 the nurse called my attention to a tumor the size of a hazel nut, in the occipital region just above the occipital protuberance, below the site of the original tumor and similarly situated in the median line. This tumor had been noticed by the patient several days previously, but being apprehensive of the necessity of further surgery, he had said nothing about it.

The tumor was painless, insensitive, tense but elastic, and apparently subperiosteal, as it did not have the feel of a recent gumma, but appeared to contain fluid. Mindful of the conditions present in the previous tumor,

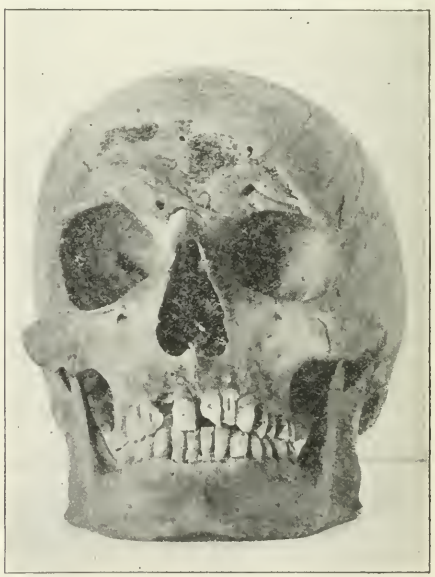

Fig. 2.

I made a tentative diagnosis of hemocyst, probably connecting with the longitudinal sinus, and suggested an exploratory operation. This was consented to Oct. 21. The tumor now measured about 1 cm. in diameter.

Under 2 per cent. cocaine anesthesia, the tumor was

exposed and proved to be, as was surmised, a cyst connecting with the longitudinal sinus. In manipulating this cyst it ruptured, giving exit to a moderate quantity of dark, perfectly fluid blood. This blood had escaped from the sinus through a circular necrotic opening in the skull, about 1 cm. in diameter. The edges of the opening in the bone were rough and eroded, but the disease of the bone apparently did not extend more than three or four mm. from its edge.

The diseased bone was removed and the wound treated as was the previous cranial wound. There was very slight hemorrhage from the longitudinal sinus immediately following the operation. Rather free venous oozing, however, began a few hours later, which was fairly well controlled by light gauze packing. As the delirium improved after the operation, and I was chary of producing any intracranial pressure if it could be avoided, the moderate oozing was not a source of much concern.

Oct. 24 the oozing of blood became so free that the wound was packed a little more firmly with gauze saturated with adrenalin solution. This satisfactorily reduced the hemorrhage but did not check it altogether, a slight amount of venous oozing continuing until the close of the case. The adrenalin dressing was stopped two days later.

The wound remained aseptic throughout and at the time of death was almost closed. The patient grew steadily weaker after the second cranial operation, his stomach became more and more intolerant, insomnia and delirium increased, and he finally died in coma Nov. 6, 1913.

No autopsy. I regret to say that no radiographs were taken.

Remarks.—In many respects the foregoing case is unique and worthy of special comment.

Syphilitic osteomyelitis—both the diffuse and the circumscribed varieties—is very familiar. This consists of : (1) an osteoplasia—ossifying osteitis—resulting in parenchymatous exostosis, which may either become permanent or break down; (2) destruction of bone from (*a*) pressure innutrition, (*b*) secondary mixed infection.

In all these conditions, both the objective and the subjective symptoms—pain, swelling, and tenderness—are marked. The characteristic nocturnal exacerbation of pain—or perhaps nocturnally limited pain—is almost always present, in greater or less degree. As the process is generally subperiosteal, the pain and the destruction of osseous tissue are easily explained by the presence of syphilitic neoplasm confined between unyielding bone on the one side and a dense, relatively unyielding, sensitive tissue—the periosteum—on the other. It will be noted that the subjective phenomena in the case herewith reported were quite different.

Spinal osteomyelitis due to pus organisms—notably to the *Staphylococcus pyogenes aureus*—leading to caries or necrosis, usually is insidious in its early stages, but an abscess eventually forms and betrays the existence of the infective process. Save in the fulminating type of osteomyelitis, acute infections of the bone are not likely to present severe pain or high temperature and other evidences of constitutional disturbance. On the other hand, syphilitic bone disease in general, while not producing temperature or other constitutional symptoms, is generally attended by pain and marked tenderness from the very beginning.

The case herein described certainly also differs from the classic description of rarefying or erosive syphilitic osteitis in which subperiosteal and intracanilicular (Haversian canal) cell infiltration and proliferation destroy the bony tissue proper and make it light, brittle and porous, the marrow eventually replacing the bone. (Interstitial gummy infiltration, diffuse or circumscribed, followed by atrophy.) This process is very slow and as a rule not destructive in the same sense as was that in the case under consideration.

Syphilis of the vertebral column is rare. Fournier in his vast experience has seen but two cases. The lesions thus far described in such cases have been typically gummatous.

As might be expected, any part of the vertebral column may be involved. The lumbar region seems to be the favorite seat of the process. The cell deposit may be either circumscribed or diffuse, involving not only the vertebral bodies but also the spinous hypophyses and the posterior vertebral arches. In one of Fournier's cases, the third and fourth lumbar vertebræ (posterior portion) were infiltrated by gummy deposit. The intervertebral cartilages were destroyed, the posterior longitudinal ligament thickened and softened, and one of the spinous hypophyses involved.

Caseated detritus of bone tissue, and of syphilitic neoplasm especially, has been noted as characteristic of syphilis of the vertebral column. This forms a yellowish, puriform mass, in which respect the process resembles tuberculosis. The slow evolution of syphilis involving the cranium and the spine is in marked contrast to that of the lesions in my case. It is unnecessary to contrast the local conditions. The description already submitted speaks for itself.

Classical syphilis of the cranium has been described as appearing in two forms, viz., (*a*) The "ulcerous"; (*b*) the hyperplastic. To these forms, I believe—for reasons which will hereinafter appear—we may tentatively add (*c*) the dystrophic.

The term "ulcerous" is objectionable, as it is made to cover blanket-wise, two distinct varieties of syphilitic bone disease, viz., (1) the necrotic and (2) the carious.

Fig. 1 shows that the various processes may be combined. The combination of syphilitic bony "upbuilding" and destruction in the same subject, as shown in one of these skulls is striking. In Fig. 2 is shown a syphilitic skull in which the entire structure was light—rarefaction. The area surrounding the frontal caries, while elevated, was thin and porous.

The hyperplastic change precedes the ulcerous, although, it must be admitted, the hyperplasia is not always recognized. The hyperplasia is either supradural, or subperiosteal and destroys the bone by pressure innutrition and erosion from without inward—*i.e.* from periosteum to bone—or from dura to bone. Pain and tenderness are usual. Severe headache is frequent. The condition often is associated with pachymeningitis. The frequent association of meningeal involvement with the gummy process in the bone is an all-sufficient explanation for some errors in diagnosis.

Where complete destruction of the bone occurs in classical cases a sequestrum forms. In caries the process progresses from the bone periphery inward, and is preceded by a softened gumma with subsequent erosion. As is true elsewhere, the process that leads to caries may be either circumscribed or diffuse.

The cases of cranial bone syphilis hitherto recorded showed multiple lesions which must have been perceptible from the surface by palpation before destruction of the bone was noted.

Commenting on the "annular" form of cranial bone syphilis, Fournier spoke of the hyperplastic ring about the base of the perforating lesions. This was noted in my case and, as I have already re-

marked, suggested the conditions found in cephalhematoma of long standing.

A prolonged process of softening and gradual bone destruction—caries or bone death in mass, typical necrosis or both, quite uniformly has been observed in such cases. The lesions generally have been noted at about the center of the bone, *e.g.* of the occipital, parietal, or frontal bones. In an unrecorded case of my own, practically the entire frontal bone was necrosed, the patient dying of septic meningitis.

I have not succeeded in finding a recorded case of bone syphilis simultaneously involving both the cranium and the spine.

It is worthy of comment that the cases of cranial bone syphilis hitherto reported have been institutional cases, in which neglect and bad hygiene have been dominant elements. In this respect the case herewith presented was the direct antithesis of the recorded cases.

In the case herewith recorded the features, which are worthy of special comment, are: (1) Combination of cranial and spinal bone syphilis; (2) Absence of symptoms of coarse brain disease; (3) Slight impairment of the mental faculties; (4) Insidiousness of development of symptoms; (5) Absence of paralysis other than of the bladder; (6) Freedom from cranial pain; (7) Apparent absence of local syphiloneoplastic conditions which could account for the death of bone by pressure-innutrition.

The association of disease of the cranial bones with the spinal bone syphilis requires no consideration save to note its rarity. Relief by the exophthalmos of intracranial pressure probably had much to do with the absence of ordinary brain symptoms and of mental disturbances, but if it served to relieve pressure on the delicate brain tissue it certainly should have lessened pressure of intracranial neoplasm upon the bone sufficiently to prevent necrosis, even had a circumscribed intracranial mass of gumma been present—which was not the case, as proved by two operations upon the skull and coincident intracranial exploration. That the destruction of cranial bone was not due to pressure innutrition or erosion from extracranial gumma was shown (*a*) by the condition of the gummatous tumor removed at the first operation and (*b*) by the fact that the second tumor was a blood cyst which emerged from the interior of the skull after the destruction of bone had occurred.

What has been said of the absence of brain symptoms applies also to the insidiousness of the process of bone destruction, merely because pain itself is characteristically symptomatic of pressure in syphilitic bone lesions. The absence of paralysis is an additional evidence of the absence of intracranial and intraspinous pressure from circumscribed gummy lesions. In the case of the spine, the blood extravasation and cyst formation were enough to account for the bladder involvement.

From time to time for many years I have suggested that some of the typic lesions of syphilis—especially of late syphilis—are due to the trophoneurotic effect of the syphilotoxins upon the sympathetic. The typic roseola and alopecia among the early lesions and certain forms of bone syphilis in the later stages of the disease especially, seem logically explicable respectively by vascular and by nutritive disturbance from syphilotoxemia. I believe that lesions such as those which occurred in the case recorded in this paper may be similarly explained.

The relation of certain syphilitic phenomena to organic or functional disturbances of the nervous system—and particularly of the sympathetic system—certainly is manifested here and there along the whole line of morbid phenomena developed in the course of the disease. The syphilitic fever, so-called, while an inconstant phenomenon, is noted sufficiently often to practically settle the question of the relation of cause and effect. The symptoms which collectively have been termed "syphilitic fever," in common with some other febrile constitutional disturbances, undoubtedly are dependent upon the action of a special toxin upon the sympathetic nervous system. From what we know of the physiology of the sympathetic system, and particularly of those functions of the sympathetic which we call trophic, it has been inferred that the majority of fevers—if not all—are directly dependent upon the action of toxins upon the sympathetic ganglia, with consequent disturbed metabolism and the usual phenomena of fever. Similarly the syphilotoxins may produce so profound an impression upon the sympathetic ganglia that the trophic function of this portion of the nervous system is disturbed, with an attendant perversion of tissue metabolism, excessive heat production, and the accumumlation in the system of the toxic products of perverted physiochemical change. The fact that the so-called syphilitic fever is not a constant phenomenon, but affects only an inconstant portion of individuals affected by syphilis, probably is explicable by varying individual susceptibility, hence the theory that the syphilitic fever is the result of the action of syphilitic toxins upon the sympathetic nervous system obviously does not necessarily imply that the syphilitic fever is a part of the natural course of the disease. We know that different individuals constitutionally are differently affected by organic poisons. If it is fair to infer that, because of special susceptibility, the nervous system of certain individuals may be morbidly impressed by other toxic disturbances to which the majority of individuals are immune, it certainly is fair to assume that in case of an organic poison so powerful as the toxins of syphilis, with which a large number of individuals inevitably are poisoned, certain special and exceptional phenomena may be produced in some persons.

Clinically, it would appear that the syphilitic toxins not only have a peculiar affinity for the sympathetic system, but that this affinity is particularly marked in the case of the upper or cervical portion of the sympathetic. The proportion of lesions about the head, face, and mouth is relatively much larger, even under the best of treatment, than in other portions of the body. The parts supplied by the fifth cranial nerve appear to be particularly susceptible.

The vasomotor disturbance that underlies the development of the roseola is substituted later on for a more or less pronounced trophic disturbance, as manifested by the heaping up of neoplastic material, the development of pus or puruloid material, the occurrence of ulcertations, etc. *Pari passu* with the supervention of this trophic disturbance in the skin, we have a similar condition in the pharynx and mucous membrane of the mouth, as evidenced by the development of mucous patches, ulcers, and macular eruptions, the latter being particularly marked upon the roof of the mouth.

On careful observation of successive crops of lesions in classical syphilis it will be found that the tendency to destruction of tissue and to the involve-

ment of various important functions of the body grows more pronounced as the case evolves. We see, therefore, in watching a case from its inception, the gradual supervention of a trophic upon a vasomotor disturbance and as the case progresses this trophic aberration becomes more and more pronounced until finally, in the period of the so-called tertiary and parasyphilitic phenomena, we have marked destruction of tissue in various situations—a destruction so marked as to have led at one time to the impression that the syphilitic "poison" produced in such instances corrosion of the tissues. In the absence of a marked corrosive property of the syphilitic toxins—and as we know its property of infection decreases in virulency as the case progresses—the logical explanation of many of the serious effects of late syphilis would seem to be the theory of trophoneurotic disturbances.

The apparent trophoneurotic character of the manifestations of syphilis is most pronounced in the late secondary and tertiary lesions. I have long been impressed with the peculiar course of some of the osseous lesions of late syphilis, particularly those affecting the face and head. It has seemed to me that the destructive effects of the disease upon certain bones is greatly disproportionate to the objective and subjective phenomena which precede bone death.

The objective symptoms that precede the necrosis *en masse* of various parts of the palate, superior maxillary and nasal bones seem comparatively slight when we take into consideration the fact that the affected bone is entirely destroyed. The first objective phenomena perceptible in necrosis of the parts mentioned are incidental, not to destruction of the bone, but to an attempt on the part of nature to rid the tissues of offending foreign material. Thus cases occur in which the greater portion or even all of the palatal processes of the superior maxilla is entirely destroyed, yet very little evidence of trouble is apparent until suppuration occurs, with a small point of ulceration of the soft parts covering the bone and the discharge of a quantity of pus so small as to be entirely disproportionate to the extent of the morbid process. On passing a probe into the small sinus thus formed, one who is not thoroughly conversant with the peculiarities of such cases is likely to be surprised to find that large portion, or perhaps, all of the bone is dead and perhaps loose in its bed. In most syphilitic lesions and in processes other than syphilitic, which produce necrosis or caries of bone, there exists prior to the death of the osseous structure, more or less pronounced objective phenomena in the way of pain, swelling, and deformity of the part; these symptoms indicating the existence of proliferated inflammatory material which subsequently cause, by simple pressure, destruction of the vitality of the bone. Syphilis of the bone or periosteum occurring early in the course of the disease is accompanied by relatively more prominent objective phenomena than the late lesions which now are under consideration; yet at the same time they rarely are followed by caries or necrosis. These processes, it seems, are reserved for the late secondary or sequelar period of the disease. It thus will be seen that, although the local process is apparently more severe in early cases, destruction of the vitality of the bone is not so likely to occur. There is a marked difference between the nodes and diffuse subperiosteal swelling of early syphilis, and the condition of the bone and periosteum, which precede necrosis *en masse*, or even caries, in the late stages of the disease.

In addition to the disproportion between the degree of destruction of bone and the objective phenomena preceding such destruction, another point worthy of comment is the fact that syphilis possesses the power of dissecting out definite portions of osseous tissue—apparently by cutting off their nutritive supply—in a manner as cleanly as it could be done with a knife. Cases of late syphilis are common in which the intermaxillary bone, portions of the alveolar process of the axilla, the malar bones and the ossa nasi have become necrosed and loosened and have required removal. These fragments of bone in many instances present a conformation as natural as in their healthy condition.

In late syphilis there seems to be a special predeliction for those parts supplied by the fifth nerve, which further lends color to the suggestion that the portion of the sympathetic system which supplies these parts is particularly sensitive to the syphilitic process.

The tendency to unilateral destruction of osseous tissue in some cases is especially marked. Thus either the palatal process of the superior maxilla or the superior alveolus of the same bone, may necrose without the corresponding portion of bone becoming affected. Indeed, it would seem that in many instances in which necrosis attacks the bones of the face, it is impossible to check the process until the line of demarkation represented by the anatomical outline of the affected bone has been reached.

I have seen numerous cases in which that portion of the superior maxilla corresponding to the intermaxillary bone was dissected out by the syphilitic process with resultant loss of the incisor teeth, the remainder of the jaw remaining intact. There appears to be a peculiar predilection of late syphilis for this portion of the jaw. Cases are frequently met with in which caries occurs in this situation with a consequent loss of one or more perfectly healthy teeth.

In considering the toxemic trophoneurotic character of the late lesions of syphilis, I do not ignore the fact that syphilis may act directly upon the nervous system in several different ways, *e.g.* (1) By the direct effect of syphilitic cell deposit upon the nerve cells or fibers, or upon the membranes of the brain and spinal cord. (2) By toxic nutritional disturbance and cell changes in the membranes of the brain and spinal cord. (3) By cell infiltration in and about the blood vessels, inducing circulatory obstruction. (4) By proliferation and organization of connective tissue, which remains after the syphilitic neoplasm *per se* has resolved.

There probably is a difference in the late and early forms of syphilitic lesions in the manner in which the trophoneurotic element is made manifest. Thus it may be due: (1) to a direct action of syphilitic toxins upon the sympathetic nervous system; (2) to direct pressure of cell infiltration upon the nerve tissue; (3) to a disturbance of function and nutrition of the nerve structures by interference with blood supply.

In considering the possible relation of trophic disturbances to destructive syphilitic processes, it is well to remember the familiar physiological experiment of section of the sympathetic in the neck of the rabbit. The same experiment also is interesting as bearing upon the faucial congestion of early syphilis. The reddening of the ear of the rabbit,

and the inflammation and sloughing of the cornea incidental to section of the sympathetic certainly are suggestive. Carrying the analogy of this physiologic demonstration a little further, we may recall the serious corneal trouble that sometimes results from herpes frontalis and orbicularis.

Conclusions:—1. Serious destruction of the bones of the cranium and spine may be produced by late syphilis without either local symptoms referable to the bone disease or disturbance of brain and nerve function.

2. Such cases are due, not to pressure innutrition of bone or to "corrosion," but to perversion of nutrition—bone dystrophy—induced by trophoneurotic disturbance incidental to syphilotoxemia, affecting especially the sympathetic.

3. This variety of syphilitic bone destruction affects by preference the bones of the face, but may, as shown by my case, affect the cranium or the spine, or both.

4. The process shows a special predilection for parts supplied by the fifth nerve.

5. The process may or may not be associated with gummatous infiltration in other regions.

6. Treatment, while in the main antisyphilitic, is never effective without surgical intervention. The surgery of syphilis is all important.

7. Exophthalmos is a "safety valve" in cases of intracranial pressure, which undoubtedly existed in my case, although it had nothing to do with the destruction of bone.

OBSCURE CAUSES OF DISEASE.*

By W. STANTON GLEASON, M.D.

NEWBURGH, N. Y.

The desire to live, and live as long as possible, has always been inherent in the minds of men. To enable every man to foster this fond hope and help him, if possible, attain the biblical three score years and ten is the aim of the medical scientist and the wish of the physician. When Metchnikoff and his coworkers announced to the world that the large intestine was the laboratory from whose reactions senile decay evolved, a new vista of possibilities as to life extension was opened to the investigator. These intestinal causes of disease are as yet somewhat obscure, but we are reasonably certain they are causes from which bacterial toxins gain entrance into the human body through some break in the usually normal line of defense. Apart from intestinal toxemias there are also important poisons which can be generated in the human body from deficient oxidation of food products in the metabolic change, causing an excess of uric acid. The effect of the intestinal poisons and also the byproducts of defective metabolisms is to limit the perfect action of certain cells or to materially retard their development.

Our present-day knowledge of toxic products, their influence on the cell, and the general disturbance of the proper correlation of organs, is due to the effective conjoined work of the clinician and laboratory worker. Through their labors we are shown how the vitality of the cell can be protected from extraneous products, and in this protection normal cell growth advanced. These primary results show the possibility of increasing the length of human life to be more real than imaginary. Carrell has succeeded in growing living tissue outside the human body; the best we can do at the present time in the body is to protect living tissue from degenerative changes.

The understanding of one of the most prominent obscure causes of disease as far as our limitations will permit is based on the knowledge of protein digestion. Through the investigations of Kutscher and Abderhalden, and the epoch-making split protein announcement of Vaughan, much of the mist of the past has faded away as regards the ultimate of protein digestion. A comparison will show our present enlightenment. Sir Michael Foster wrote in 1891: "At all events, the greater part of the proteid material of the food enters the blood as peptone or in some other form, and is carried as proteid material to the tissues." Science today determines that proteins are now broken up in the intestines into amino acids; these acids are absorbed into the blood stream and are carried through the body. Mendel states protein metabolism has at length become a question of the behavior of the amino-acids in the body—their uses and fate. Vaughan, through his brilliant work, shows us "That the body to be in perfect health should have all the cells functionate in harmony. And as these cells are living, growing and multiplying they must have a supply of natural nourishment, and as these cells are made up of protein to a large extent, they must be furnished with protein food. Vaughan divides the digestion of protein substances under two heads: Parenteral, or the digestion of protein outside of the intestines; and enternal, or the digestion of the protein substances in the intestines. Parenteral includes all the proteins taken up in minute quantities by the respiratory tract, also small quantities taken up digested or undigested from the intestinal tract. Proteins are also thrown into the system through the agency of serum and vaccines in varying amounts. In infections living proteins gain entrance to the body, increase and change the body proteins into foreign proteins; the ferments of the body will take care of this great influx of foreign protein up to a certain point. But if the balance is seriously overweighted an active febrile phenomena bursts out. The proteins entering the human system through the intestines are split into amino acids and synthesized into specific proteins. The cells of all the organs take up the same protein food. The force which accomplishes this change from protein to individual cell is called a ferment. The cells of each organ have their own ferments peculiar to the organ, and these ferments act to defend the cells against foreign protein products." In intestinal indigestion the protein element can generate powerful toxins. It is well proven that undigested protein, especially in the large intestine, can generate elements that are most energetic poisons. Mellanby and Eppinger contend that under certain physiological conditions, poisonous amino acids are formed in the colon which exert a powerful influence in the general circulation, as does a gland with an internal secretion.

Eastman shows that toxemia from the colon can come from four causes: colitis, adhesions, colon dilatations with viceroptosis, and stasis. Virchow and Pilcher believe that plastic adhesions may form about the colon as a result of a toxemia having its origin within the large intestine. Bassler, Runneford, and Heyde, isolated various forms of anaerobic bacteria which they judged were factors in the formation of adhesions about the colon and vermiform

*Read before the First District Branch of the Medical Society of the State of New York, October 8, 1914.

appendix. Adami also supports the theory that pericolonic adhesions may produce stasis through the agency of bacteria. Adhesions about the colon nearly always produce local or reflex symptoms in some portion of the abdomen, especially of the stomach. Mayo states that cases of colon stasis with flaccid abdomen can possibly be cured with a vegetable diet, but where there is a firm abdomen and direct evidence of partial obstruction the case becomes surgical. Armstrong holds that within the past one hundred years the flesh intake of man has increased four times; it is distinctly pointed out that the proximal end of the large intestine favors only the digestion of vegetable substances. Therefore, it is only a fair supposition that meat substance would naturally provoke indigestion with toxic products if conditions were not absolutely normal in the colon. Lane believes that the human family are better off without a colon, because it is the seat of so much human misery; the supreme court in surgery however hand down no such radical decision. The general practitioner and the surgeon are alike impressed that a survey of the systemic consequences from infections originating in the large intestine forces on us a new viewpoint in medicine and surgery.

Any defect in the large intestine, be it either mechanical or a fault in its function, results in a varied flora of bacteria within its walls. These microorganisms are of the anaerobic putrefactive type, and acting on protein bodies produce toxic products such as indol, skatol, and paracresol. These poisons, being reabsorbed into the blood, cause serious disturbance in the digestive, circulatory, and nervous systems, and also a general irritation of the harmony of action of all the organs of the body. Experimental studies from the Institut Pasteur, Paris, show premature senile changes induced in animals by the daily feeding with one of the indol, phenol, or paracresol compounds. These changes are strikingly similar to those pathological changes common to the aged, such as the increased formation of connective tissue, consecutive atrophy, and gradual disappearance of the parenchyma of the vital organs.

Focal infection is closely allied to local and general disease, and frequently bears an important influence on the general well-being of the individual, from the difficulty in locating its source of activity. Focal infection is essentially an obscure cause of disease, and the focus of infection may come from any part of the human body. Usually its origin is in the head, in the form of an alveolar abscess, tonsillar abscess, poor teeth, and various chronic sinus conditions. It may also come from chronic appendicitis, salpingitis, prostatitis, etc. Acute rheumatic fever is considered by Rosenow of focal origin, he having proved the presence of the infectious organism in joint fluid. Billings considers focal infection as largely responsible for arthritis, cholecystitis, pancreatitis, etc. Billings also holds that when the defences of the body are down by overwork or exposure the individual is especially susceptible to focal infection. In investigating obscure causes of disease the importance of early recognition of the focus of infection must be prominent in the physician's mind. Any break in the normal in any part of the body is worthy of our attention when the well-being of the patient is in question.

Through the courtesy of Dr. Charles G. Kerley I have had access to his unpublished article, "Disorders in Children Arising from Derangement of Function." In this manuscript Dr. Kerley brings out very clearly an obscure incipient cause of disease in children. He points out that the rapidly growing period of life is the time metabolic changes are most active, and is also the time when we are apt to have metabolic defects in the utilization of complex foods. The faulty deposition of salts probably produces rachitis in children. Protein is rarely a factor in childhood diseases. But in the active child it is the use of energy foods such as milk, butter, and especially sugar, that gives rise to trouble. For it can be well assumed that nearly every healthy child of well-to-do parents receives two or three times as much energy food as the body requires. It has been demonstrated that the end results of normal carbon oxidation include the production of heat. In the defective metabolism of carbon in children, toxic products are probably formed which produce periodic disorders of function such as recurrent noninfectious colds, recurrent noninfectious bronchitis, with or without asthma, recurrent vomiting, recurrent fever, also eczema, so-called bilious attacks, with or without vomiting. Recurrent noninfectious bronchitis occurs in fall and winter, with a history of frequent attacks with or without asthma, and the child is kept within doors. These children bear milk and sugar badly, and the trouble is no doubt due to faulty oxidation of too highly energized nourishment.

Recurrent vomiting can be associated with other forms of disorder, as bronchitis, asthma, and eczema. Acetone may be present in the urine. It is believed that these cases come from faulty oxidation of fat, sugar, etc., given habitually beyond the child's power of oxidation. The treatment for the recurrent types of cold and bronchitis is to cut off sugar largely or entirely, if the case promises to be difficult, cow's milk is absolutely omitted; if the disorder is obstinate skimmed milk is allowed. As Dr. Kerley states, "time and again I have seen children three to six years of age gain from three to six pounds in removing sugar from the diet and giving skimmed milk or none at all." The carbohydrates and fats are found in vegetables, cereals, breadstuffs and meats, and supply all the heat and energy required. As to the lithemic type, individuals belonging to this group are given an internal treatment with soda alone or combined with sodium salicylate. This treatment applies also to recurrent vomiting.

Uric acid: Since Alexander Harg published his memorable work, "Uric Acid in Causation of Disease," much thought and attention has been given this obscure agent in the consideration of obscure causes of disease. Investigators are still far from unanimous as to the origin of uric acid in the system. We are told that the uric acid in the urine is derived from either cellular metabolism or directly from food; then again that uric acid is made in the epithelial cells of the uriniferous tubule. A moderate amount of uric acid is essential to normal health; an overproduction of uric acid is abnormal, and a serious menace to the human body. We find an overproduction of uric acid in those individuals who have abnormally small lungs. In these cases even with a most careful regulation of diet and régime it is difficult to reduce the overproduction of uric acid. The cause of this excess is the inability of the individual to take in sufficient oxygen from the air to oxidize fully the protein substances, and the throw down is uric acid and brick dust

urine. These patients are supposed to remain in reasonably good condition, until through persistent irritation toxins from other sources overwhelm the system. A second class of patients are those who persistently overindulge in foods rich in starches, sugars and fats, and possibly proteins. The carbohydrates being oxidized quickly exhaust the supply of oxygen in taking care of the more easily combustible compounds, and there is not enough oxygen left to oxidize the protein. The consequences are general metabolic disturbances and defective assimilation and nutrition. With this train of symptoms follow digestive limitations and the consequent formation of toxins from the intestines, and a high indicanuria. There is another type of which there is impairment of the liver functions. This faulty action of the liver again limits the oxidation of protein with a resulting overproduction of uric acid.

Uric acid excess from any source is important, and its persistence, if unchecked, cannot help but be an ever-increasing menace to the integrity of the organs and an irritant to the nervous system.

From our present viewpoint, what are the effects of uric acid excess and intestinal toxemia on the human system? The results are in comparison with the degree of irritation and poisoning, and the length of time the toxic elements have been gradually increasing their influence. It has been shown that the constant accumulation of uric acid in the body is primarily irritating to organic structure, and also to the nervous system; then finally unless checked produce permanent pathological changes.

Intestinal toxins are perhaps more rapid in their effects and if unrestricted create a general disturbance of the body functions, with ultimate senile sclerosis in the tissues of organs and blood vessels. The final effects of both uric acid excess and intestinal toxemia seem to be so closely interwoven, from their bearing one upon the other, that they cannot be separated. Then again, as Taylor states, "there are so many contradictions at present on the interactions of internal organs that the student becomes confused and we look forward when a work will be written by an authority on autointoxication on the basis of the functions of the internal organs in the light of metabolism."

It is a reasonable argument, however, to consider that the basic factors in arteriosclerosis and gradually rising blood pressure are due to systemic toxins probably from the colon and also from defective metabolism. Appreciating our limitation, we strive to eliminate these toxins with ofttimes pleasing results, especially when the increased blood pressure is not associated with kidney lesion. Blood pressure is a symptom with a hidden cause; treating the cause, we usually limit the blood pressure and save our patient from possible terminal effects as arteriosclerosis, kidney lesion, or even apoplexy. The treatment of "focal causes of disease," and "metabolic disturbances in children" has been considered under their proper head. We would place excess of uric acid and intestinal poisoning under the same general plan of treatment. Each case should be individualized and diagnosed, and the habits of life carefully investigated. An adult requires about twenty-five hundred calories of food in the twenty-four hours, or over twenty calories to the pound of body weight. The average man needs fifty grams of protein food daily from all sources. Drawing our deductions from our present light of knowledge in the behavior of proteins as being a fertile source of systemic infection, and as L. F. Bishop states, "we must not disregard the teachings of the chemistry of our bodies." Therefore, we must limit our protein intake to absolutely body requirement, or even less, for we know living protein tissue can be built up by both protein and carbohydrate elements. Taylor points out, "that it is immaterial to the body growth whether the seroalbumin protein comes from plant or animal life. The carbohydrates are freely permissible, except limiting the use of sugar and sugar combinations. The department of nutrition makes cheese a safe substitute for the more potent proteins. Fruit acids should be withheld at times but are generally advantageous. The free use of water is often a detriment, for the surplus may pass directly to the colon, causing overdistention; in arteriosclerosis an overabsorption of water will throw an extra burden on the already embarrassed circulation. The best form of nourishment in extreme excess of uric acid are eggs and milk, for as Taylor states, they are purin free and uric acid is derived from purin bases.

A minute and detailed application of dietetic principles is beyond the scope of this paper; individual symptoms require individual attention. These patients should avoid overeating, and should use proteins in great moderation, carbohydrates with judgment, and common sense in everything. But little medicine should be used. A proper equalization of exercise and rest, both mental and physical, is important. Exercise according to individual limitations. Rest sufficient to repair daily waste, be it either in days or weeks, is quite essential, the proper prescribing of rest requires good judgment on the part of the physician.

Crile tells us that animals deprived of their proper rest show great deterioration of their vital forces. The strain and pressure of active modern life without adequate relief paves the way for those toxemias which will undermine the active forces of the most energetic. We have no intestinal antiseptics today except the Bulgarian bacilli, and they are but an adjuvant to the wise application of exercise, fresh air, and diet. Beyond regulating the bowels with some mild laxative as Russian oil, medicine takes an inferior position in the curative process.

In closing this paper I feel a deep sense of obligation to the laboratory worker for the light he throws upon possible obscure causes of disease. The scientist and clinician must labor together, the scientist pointing out the method and the practitioner of medicine applying it for the common welfare of mankind.

113 GRAND STREET

INTESTINAL STASIS.

BY FRANK R. STARKEY, M.D.,

PHILADELPHIA, PA.

IT is not surprising that the subject of intestinal stasis has recently played so conspicuous a part in medical literature, for now that the term is used synonymously with autointoxication the manifestations of this condition are believed to be so wide as to cover almost the entire realm of chronic diseases from neurasthenia to spinal sclerosis, from indefinite muscular pains and lumbago to arthritis deformans, and from the slightest digestive disorders to cancer of the stomach and pancreas (Lane). The entire gamut of diseases has been attributed to intestinal stasis and subsequent autointoxication, due to resorption of putrid intestinal contents which had not been sufficiently catabolized to reduce them to harmless substances. The treatment that has been suggested has been as extremely varied as have been the ideas as to etiology; ranging all the way from dietetics to Lane's extreme surgical methods. The pathology is also in dispute, graduating from the slightest retardation of the passage of the intestinal contents through the ileum and colon with subsequent ordinary constipation, to adhesions, fibrous bands, intestinal kinks, and even intestinal obstruction. The multitude of symptoms which have been and can rationally be attributed to this condition, include neurasthenia, neuralgia, so-called rheumatism, *i.e.* such pains as follow the consumption of goulash and other indigestible conglomerations, to ocular defects and disturbances of hearing and symptoms referable to the male and female organs of generation. This is easy to understand when we realize the great amount of change to which the protein molecule is susceptible. It has been shown that the protein molecule is capable of rearrangement into not less than 20,000,000 combinations. It is also true that the intestinal tract contains sixty different varieties of bacteria, each with its individual chemical predilections, etc., so the variety of poisonous products that can be elaborated within the intestinal canal is almost beyond computation. It is not the retention of uric acid in the system that produces the symptoms of the so-called uric acid diathesis. They are the result of deficient oxidation or interrupted catabolism and the retention of purin or alloxuric bases like xanthin, adanin, guanin, etc. All of which are highly toxic and are normally reduced to harmless substances by further oxidation. The term, intestinal stasis, originated with Sir Arbuthnot Lane, whose definition of intestinal stasis is: "Such an abnormal delay in the passage of the intestinal contents through a portion or portions of the gastrointestinal tract as results in the absorption into the circulation of a greater quantity of toxic or poisonous materials than can be treated effectually by the organs whose function it is to correct them into products as innocuous as possible to the tissues of the body." The line of defense between the intestinal tract and circulating blood is made up as follows: the ferments in the stomach and intestines, including pepsin, trypsin, steopsin, amylopsin and enterokinase, making up the digestive juices, and the friendly bacteria of the intestinal tract; the intestinal mucosa; the mesentery glands; the liver and the glands of internal secretion; the emunctories; the intestines; the kidneys; the skin and respiration. According to Lane, the main cause of intestinal stasis is visceroptosis and formation of kinks. These kinks, according to Bainbridge,[2] obstruct the lumen of the intestine and cause damming back and infection of the contents, and general slowing of the drainage canal. According to Eastman,[3] the subject of colonic toxemia may be studied under four headings: (*a*) colitis, (*b*) adhesions, membranes, and kinks, (*c*) colon dilatations and visceroptosis, and (*d*) stasis. It may be remarked here that in the presence of adhesions or kinks of sufficient magnitude to cause stasis a dilatation would be a necessary consequence. Adami[4] believes that through the action of bacteria, which he has proven pass freely through the intestines to the peritoneal cavity, adhesions are formed. He has also shown that when these bacteria are of mild virulence the inflammation which they cause inhibits their own growth so that the fully formed adhesions are sterile, the bacteria causing them being found only in the mucous membranes of the intestine itself. Bassler[5] has described a bacterium which he believes to be a causative factor in the development of adhesions and has named this bacterium the *Bacillus adhæsioformis*. He has found this bacillus in eleven cases. In dogs adhesions of a strong membranous nature are almost the invariable rule, even when the animals are apparently in perfect health. Colon stasis in the dog seems to be a constant phenomena. The *Bacillus adhæsioformis* of Bassler is anaerobic, is a saprophyte and as stasis favors the growth of the ordinary colon bacillus, and thus the consumption of oxygen from the intestinal contents, it will be seen that growth of this saprophyte is favored indirectly by intestinal stasis. Hewes has shown that spasm or abnormality of peristalsis of portions of the gut, with stasis of contents or gas, may occur in portions far removed from the actual seat of the lesion without the finding of any anatomical variation in the portion where the function is disturbed, for example; disturbances of the stomach with imperfect emptying of the contents, may occur in cases where no distortion of the stomach or duodenum is present and where the only abnormality is adhesions about the cecum and stasis of contents. Wilms' stasis or cecum mobile, can be considered an illustration where downward displacement of the colon acts as a causative agent in intestinal stasis. In this case the column of contents of the loaded ascending colon by its weight and hydraulic pressure dilates and pushes the cecum downward into the pelvis. Colitis is quite a constant accompaniment of stasis, but stasis is not necessarily an accompaniment of colitis, in fact the reverse may be true. Colitis, stasis, adhesions, or ptosis may cause[6] any of the other three conditions. Therefore, the tendency of these conditions to act in a vicious circle, will be seen. In the pathology of this condition the role of the ileocecal valve is commanding considerable attention at present. In 1878, Bull,[6] after a painstaking series of experiments, concluded that in the living body the ileocecal valve is impervious to fluid but when the bowel is overdistended by air the valve is rendered incompetent. Dawson,[7] 1885, was able to confirm these conclusions by experimentation on the cadaver. Most anatomists

and physicians of the present day concur in these findings and Ziemssen[8] and Heschl,[9] after exhaustive studies, found that in the normal individual the ileocecal valve was a competent barrier against return of the contents of the cecum into the ileum.

On the other hand a large number of observers, including Boyd, Hammeter, Church, Gruetzner,[10] and others, by forcing oils and other substances by rectal enemata past the ileocecal valve, have attempted to disprove its competency. Cannon and others, studying peristalsis and antiperistalsis by means of the Roentgen rays, have been able to establish firmly the truth of the efficacy of this natural gate between the ileum and cecum. It must be remembered here, however, that Senn showed that competency of the ileocecal valve is overcome by rectal inflation when a pressure of one and a half to two and a quarter pounds is employed. Senn's experiments have been confirmed by Behrens and others. Holzknecht and Singer[11] speak of the frequency of ileocecal valve incompetency in chronic constipation. Groedel[12] reported a number of cases of ileocecal valve insufficiency which he had demonstrated by means of the Roentgen rays. Many other writers have seen ileocecal valve incompetency in connection with intestinal disturbances. The ileocecal valve is almost always normally competent in all vertebrate animals. Case[13] reports having observed reflux of bismuth in the ileum, which had been ingested. He witnessed this in more than seventy cases after the ileum had become emptied of its contents, in ten or twelve hours after the bismuth meal. The ileum was again found to contain this substance after a lapse of twenty-six hours, though no more bismuth had been taken in the meantime. In a series of two hundred cases reported by the same author, thirty-three, or one in six, showed ileocecal valve incompetency when tested by bismuth enema. Again in 1913 he reports an additional series of fifteen hundred persons who had been tested by use of bismuth and Roentgen rays, in which two hundred and fifty, or one in six, showed ileocecal valve incompetency. Most of these patients suffered from constipation. The same author reported an additional five hundred cases in which the same condition occurs in the same ratio, one to six. It may be observed that the ileocecal valve depends for its competency or efficacy largely upon the oblique direction in which the ileum enters the cecum. This is considered by a great majority of anatomists as a necessity to its imperviousness. According to Arthur Keith[14] there are muscular fibers situated at the ileocecal orifice which are evidently designed to secure that orifice from reflux of intestinal contents from the cecum. In the distal portion of the ileum there is, normally, an excess of muscular fibers causing distinct thickening of the circular muscular coat which seems to be endowed with a sphincter like function. This sphincter relaxes in front of a persistaltic wave allowing the passage of the mass into the colon and contracts behind it, guarding against regurgitation, thus acting somewhat as a bulb syringe. In the author's opinion, based on careful study of a large number of cases, patulency of the ileocecal valve is not necessarily dependent upon adhesions around or malformations of the ileocecal valve but may be due simply to flabbiness of the intestinal walls, causing it to sag open from sheer weakness. Among the etiological factors we may consider heredity; persons inheriting the gastroptotic habitus; congenital malformation, corpulence, in which large masses of intestinal and omental fat retard peristaltic action; inherent lack of muscular and nerve tone; visceroptosis with relaxed abdominal muscles; sagging of colon and relaxation of the distal portion of the ileum and gaping of the ileocecal valve; frequent pregnancies, which tend to lower muscular and nerve tone and predispose to intestinal and peritoneal adhesions; appendicitis with adhesions following it and deficiency in internal secretions which govern nerve and muscular tone. Adhesions are held by many to be invariably responsible for this condition and undoubtedly do play an important part in the causation of certain cases. A case was reported by the author of a young woman, twenty-five years of age, housemaid by occupation, who was in the habit of going eight weeks without having a bowel movement. This individual, who was satisfied with half a dozen bowel movements in a year, showed no signs of adhesions nor gastroptosis, although she had an enormously enlarged colon. The signs of ductless gland disturbance were conspicuous, manifesting themselves by pigmentation of the skin, vasomotor disturbances, etc. Her father, a man sixty years old, was in a similar condition.

The symptoms of intestinal stasis are extremely varied. In the milder forms consisting of constipation, anorexia with mental dullness, mild headache, abdominal distress or pain, later followed, as the case proceeds, by more marked constipation, frequently throbbing or sick headaches, gastric symptoms, more or less constant abdominal distress with paroxysms of violent pain; a variety of reflex nervous disturbances; vasomotor disturbances manifested by pallor of the skin, clammy, cold sensation, profuse perspiration, and low blood pressure or florid complexion and high blood pressure depending upon the particular poison being absorbed; asthenia; melancholia; hypochondriasis and all of the chain of symptoms that we call neurasthenia with disturbances of the special senses; asthenopia; ocular pain; oculomotor imbalance; choroiditis and even optic atrophy; symptoms referable to the organs of generation, amenorrhea, dysmenorrhea, leucorrhea, urethral and vesical irritability, and impotency. Pain in various parts of the body, articular stiffness from the mildest degree to arthritis deformans. In brief, such stiffness of joints and muscles that are usually classified under the ambiguous head of rheumatism. When not in reality referring to true rheumatic fever, these are invariably signs of gastrointestinal autointoxication.

Disturbances of the organs of internal secretion with decrease of their autoprotective power are conspicuous. Lane in his enumeration of the signs of intestinal stasis, has drawn an almost perfect picture of imbalance of the organs of internal secretion. He enumerates them as follows: "Loss of fat." In hypersecretion of the thyroid gland loss of fat is the rule. In dispituitarism again there is a distinct type where loss of flesh is conspicuous. In disturbances of the functions of the genital glands loss of flesh is frequently prominent. Wasting and relaxation of the voluntary and involuntary muscles occurs in pituitary insufficiency, thyroid insufficiency, and insufficiency of the secretions of the sexual glands. "Degeneration of the skin." Changes in the skin are conspicuous symptoms of pituitary and thyroid derangements as seen in acromegaly, Addison's disease, myxedema, cretinism, and other diseases in which the glands of in-

ternal secretion are notably involved. "The temperature of the body is subnormal." This is the rule in pituitary deficiency. Bluish color of the hands, pointed out by Lane, is common in all cases where circulation is depressed as in pituitary deficiency. The mental condition, he states, is one of apathy and stupidity. He could not paint a more perfect picture of the mental state of pituitary or thyroid deficiency. "Patient complains of so-called rheumatic aches and pains in the muscles and joints and even in the skin." These are symptoms in acromegaly. "Wasting of the thyroid gland." This is usual in advanced cases of imbalance of the ductless gland system, no matter what the origin may be. "Blood pressure may be raised or depressed." When the secretion of these glands is deficient blood pressure is subnormal. Where the adrenal, pituitary, or thyroid is over active the blood pressure is raised. "Breasts show very definite degenerative changes." The intimate relation between the mammary, sexual, and other glands of internal secretion is well known. Lane says: "the visceral organs prolapse and alter in shape, partly because of loss of fat, partly because of wasting of muscular fiber." After the time of the menopause, when the glands of internal secretion have lost much of their activity, flabbiness of abdominal muscles with relaxation and consequent ptosis of the viscera, sagging of the intestines, etc. is usual. "The patient becomes breathless on exertion." This is the case when there is a general relaxation of the bodily musculature, for the heart muscle is included. "Most of the degenerative changes that affect the muscle of the heart appear to be due to autointoxication." The internal secretions are important factors in neutralizing the substances which usually produce autointoxication, and a failure on the part of the glands of internal secretion, which permits products which are absorbed from the intestines before they have undergone sufficient retrograde oxidation, to enter the circulation, is a frequent cause of myocardial degeneration and associated with atheromatous changes in both the larger and smaller vessels. The kidneys are liable to derangement by the abnormal strain thrown upon them and degenerative and inflammatory changes result which are roughly grouped under the term, Bright's disease. Kidney degeneration of this particular type is almost constant in disthyroidism. "The hair of the head loses its color early in life and tends to fall out." The author has called attention elsewhere[15] to thinning of the hair in both hypopituitarism and hypothyroidism. "The pancreas becomes affected directly by extension of the stagnant contents of the duodenum. This results in chronic induration, inflammation, and finally cancer of the organ. Pancreatic diabetes also ensues." A close relation between perversion of the pituitary and thyroid function to diabetes is well known to all students of this subject and has been pointed out by the author many times. "Gallstones, cystitis, and cancer may be produced, besides many acute or chronic diseases of the liver." Gallstones and cystitis are especially frequent at the age of the menopause and thereafter when the function of the ductless glands is distinctly lessened. "Those diseases of the eye, which are degenerative in origin, are produced by and vary with the degree of autointoxication." The frequency with which optic atrophy and other optic degenerations are associated with pituitary disease has been shown by numerous observers.

Diagnosis.—We must first consider the history of these cases. We frequently find a history of constipation and indigestion with abdominal cramps. The constipation may alternate with diarrhea, stools are apt to be badly formed, either in small hard masses or in flattened ribbon-like formations, which is characteristic of a spastic condition, or there may be hard masses covered with mucus. When diarrhea obtains the fecal matter is usually curdy, flocculent, foul smelling, and is expelled with great force accompanied by gas. A history of faulty occupational position which favors the formation of adhesions, of acute or chronic appendicitis, abortions, peritonitis, or abdominal operations is common.

Examination.—The patient is frequently pale, sallow, with flabby face and sagging cheeks. The abdominal picture is very characteristic; pot bellied with flattened epigastrium and a distinct line of demarcation between the thorax and abdomen, frequently a deep indentation. General flabbiness and relaxation of the muscles, especially those of the abdomen. Percussion gives us a great deal of information. As a rule we are able to map out a distended ptosed stomach and colon. The *x*-ray examination, by aid of the bismuth meal, confirms percussion, and in addition we can often define signs of adhesions, kinks, dilatations, and malposition of the organs. Blood pressure is frequently increased.

The urinary findings are quite characteristic. The urine is usually scanty in amount, pale in color and low in specific gravity due to deficiency in solids. Indican is increased in proportion to the autointoxication present. The ethereal sulphates are increased. There may be albumin and casts if the kidneys are much embarrassed. The blood does not show anything characteristic.

Treatment may be divided into: Hygiene; exercise and other physical means, diet, medical, and finally surgical measures; fresh air; systematic bathing to improve elimination; exercise, walking and hill climbing, calisthenics and special movements directed toward requirements of individual cases; massage and gymnastic work are frequently valuable aids. Attention given to the diet with the object of (*a*) overcoming constipation, if present; (*b*) increasing the bodily fat and in this connection the Weir-Mitchell rest and forced feeding method is valuable; (*c*) decreasing putrefaction by lessening nitrogenous content, a liberal diet of easily digested foods, rich in cellulose with plenty of water so there will be a large moist residue remaining in the bowels, is desirable. Overloading the stomach, however, must be avoided. The teeth of the patient should be looked after and careful mastication insisted on.

Medical: Disintoxication treatment. I have used this with considerable success. All food is withdrawn for a period of from three to five days, during which time the patient is encouraged to drink water freely and large doses of a saline are administered so the bowels are copiously evacuated each day. If this is followed by the administration of lactic acid bacilli a new flora of the intestines can frequently be established, the saprophytes having been washed out and starved out in enormous quantities by abstinence and purgation, allowing the friendly lactic acid bacilli to propagate. Russian paraffin oil or olive oil, or cold expressed linseed oil are also valuable adjuncts. Where spasticity of the intestines obtains, belladonna is indicated. Where atony exists, nux

vomica and cascara are useful. If there is difficulty in inducing the patient to partake of sufficient coarse food, agar will act as a valuable substitute and assist in providing moist bulk in the intestines. The ductless glands which play such an important part in the tone of the intestinal tract should be stimulated and their function increased.[15] The mild, rapid sinusoidal current administered to the seventh and eighth dorsal vertebræ produces excellent results. I have obtained and have seen others obtain splendid results by this method. The ptosis is markedly diminished and one's treatment can be followed very beautifully by daily fluoroscopic studies of the stomach and intestines. I have seen them raised to a normal position in a remarkably short time, where there are no adhesions to bind them down. The effect of this treatment is lasting. The period required for emptying the ileum is distinctly shortened. The various kinds of abdominal supports are useful in this condition, not so much for the actual replacement of abdominal viscera to their normal position as for the support which they give to the abdominal walls and contents, facilitating the drainage of blood from the splanchnic veins, thus overcoming the splanchnic engorgement which always obtains in these cases. This relief is very prompt and very pronounced. The best of these supports, is, perhaps, strapping the abdomen with adhesive plaster as suggested by Cohnheim, Rose, and others. Next to this come various belts which can be selected according to the individual requirements of the case. The results obtained in this way are at least as good and as permanent as those following surgery, and are absolutely free from danger.

In considering the surgical aspects of this condition I am entirely in accord with the sentiments of Professor John G. Clark as expressed in his valuable article[16] in which he says: "The various ptoses of the viscera are now in the surgical proving ground and all will admit that the devising of effective ways and means of remedying these abnormalties is attended by more difficulties than is usually encountered in other fields of medicine. This difference is due to the fact that the condition is neither a disease nor a disability of a single organ but a manifestation of the general abnormal physical state of congenital or acquired origin, accompanied by more or less profound neurasthenic symptoms. The surgeon can help, at most, but a small percentage of individuals so afflicted, for although advances have been made in the operative treatment, no single measure has yet proved so efficacious as to gain general approval. It can scarcely be expected that the lifting up or even the excision or an anastomosis of offending organs can effect so complete a metabolic revolution in a patient of adult age as to result in even a moderate state of well being after years of distorted growth. That such cures can be effected is contrary to all laws." Numerous operative procedures have been devised by various surgeons, but if surgery is to be resorted to the axiom laid down by Eastman[3] is a safe one, viz, "The surgical procedure to be employed in any given case should be determined not before the operation but after the abdomen has been opened and completely explored." Again quoting this same author: "Little or nothing is to be expected from operations for the removal of pericolonic membranes which are at all extensive. The purpose of the operation should be to not put the colon out of commission but by relief of colitis and pericolitis by drainage, to put the colon back into commission." According to Bassler,[17] anyone can show that at least 18 per cent. of all people have a Lane or ileal kink and in the vast majority of these cases some delay but no toxemia exists. In 167 cases examined by this author by means of the *x*-ray, in which a true Lane kink existed, in only five cases did this kink cause definite delay. He believes that it is decidedly more reasonable to consider these bands as physiological and has many times seen them return in six months after operation.

In the author's experience in the cases which he has submitted to the surgeon for operation and the cases of others which he has studied, the postoperative history has been one of chronic invalidism with repeated operations for the correction of adhesions. An operation of this kind cannot be performed without considerable manipulation and traumatism of the peritoneum both visceral and parietal, all of which favors the formation of adhesions. Contraindication to surgical procedures: In addition to the usual contraindications of surgical intervention, including affections of the heart, kidneys, etc., persons with general visceroptosis and relaxed abdominal muscles cannot expect permanent relief. Those who show a distinct tendency to formation of adhesions should not be operated upon. Where the ductless glands are conspicuously deficient in their function little can be expected from surgery. I believe that surgery is never justified except where there is actual intestinal obstruction and that this fad of short circuiting will go out of style the same as the custom which prevailed a few years ago of promiscuous nephropexies, oophorectomies, appendectomies, and other -pexies and -ectomies.

The question of shock must not be overlooked in connection with this subject. It is well known that in these major operations, where the abdominal cavity is opened and no intestines handled, the amount of shock is by no means inconsiderable. What is this mysterious condition of depression which we call shock? In view of the radical changes that have taken place in our understanding of physics since the advent of the electronic theory, we know that the different physical manifestations of matter are simply differences in the vibration of the component electrons. The difference between the individuality of persons is not merely one of physiognomy or corporeal peculiarities but their personality depends upon the rate of their electronic vibrations. The human body is naught else but an aggregation of cells, each a world within itself, made up of various components which are finally composed of electrons vibrating in perfect unison and the entire organism attuned to vibrate in one harmonious whole. In view of all this, why should it not be reasonable and rational to define shock as a disturbance in the normal vibrations of the electrons of the organism? This would certainly conform to our recent knowledge.

THE USE OF PITUITARY EXTRACT IN OBSTETRIC PRACTICE; WITH SOME CRITICAL OBSERVATIONS ON "TWILIGHT SLEEP."

By SAMUEL W. BANDLER, A.B., M.D.

New York.

I DESIRE to discuss the use of pituitary extract in obstetrics, not with an array of statistics nor with a detailed report of individual cases, but simply hoping to convey the very favorable impression that has been made upon me after an extended use of this drug in the various types of cases as they occur in obstetrical practice over a period of years.

My experience with the technique of many physicians and my observations in the cases of colleagues with whom I have been associated in the conduct of such cases has shown me that the sterling value of pituitary extract is not generally recognized. The use of this preparation seems to be looked upon as indicated by special or urgent considerations only. The purpose of these observations is then to call attention to the value of this drug, not alone in cases where no progress is made or in cases where urgent haste is demanded, but in the conduct of the average case as it comes through the hands of the practitioner in his routine work.

No addition to our obstetric aids has been of such potent service as has the use of pituitrin. It has simplified many questions, has shortened the duration of labor in primiparæ, and most particularly in multiparæ, has removed almost entirely the necessity of applying low forceps, except in the very rare cases of emergency. (As to high forceps, indications are complex, opinions differ, and version and cesarean section come into consideration.)

Pituitary extract does not act to the same degree in all patients; a small dose in one case is very effective, whereas numerous repeated doses are necessary in other cases. It increases the pain which the patient feels, but, and this is the purpose for which we are using it, it increases the efficacy of the uterine contractions.

In selecting cases for its use and choosing the proper time, we must be guided, not by the subjective sensation of pain which the patient has experienced, nor by the frequency of the pains alone, but by the progress which is being made. Therefore it may be used in the first stage of labor as well as in the second stage.

Pituitary extract does not act unless labor pains have begun, hence it is of value in determining whether the pains which the individual feels are true labor pains. For instance: Take a case where the membranes have ruptured before any pains have begun. Periods varying from a few hours to two or three days may elapse before progressive labor begins, yet in the meantime there may occur occasional periods when severe pains follow in fairly rapid succession, only to die out shortly after. An injection of pituitrin given at this time may be of no value whatsoever; or it may add force and continuity to the pains, in which event successive injections will cause them to progress into the regular steps of a genuine parturition.

Take another instance: A patient had gone two weeks over the expected period, and had had on two occasions, at night, severe attacks of pains, coming on at ten-minute intervals, for an hour to two hours. The patient's husband, a physician, was loath to call me because he was uncertain as to whether these pains were real or not. I urged him to inform me the next time that this happened. He did so. An injection of pituitary extract was then given, and the patient went on to regular continued pains and was delivered in ten hours.

If regular pains, associated with appreciable dilatation of the cervix have once begun, the use of pituitrin increases their power and causes extremely rapid dilatation of the cervix. There is no reason why the first stage of labor should be allowed to prolong itself beyond a reasonable number of hours, with a head engaged and moulded in the brim. It occurs of itself so quickly in many cases that we may be reassured in our belief that a rapid dilatation is not injurious. For us to let nature direct this process sluggishly and indolently, fortified by the thought that no harm is done to the fetus so long as the membranes are intact, is to add hours of pain and discomfort to the patient.

While I was attending one patient in confinement another patient had been in labor with pains occurring every ten minutes, occasionally every five minutes, for over 12 hours. When I reached this patient the cervix had disappeared, and only the edge remained, but dilatation was present only to the extent of one finger. Three minutes after the first injection of pituitrin there was a marked show, and in less than two hours the cervix was completely dilated, after which the membranes were ruptured and labor was completed in one and a half additional hours.

In those cases where the Barnes bag is used, it is occasionally necessary to introduce a second or even a third bag, because, after the expulsion of the first, labor pains do not occur or recur. If, during the action of the Barnes bag an injection of pituitary extract be tried, and perhaps a second injection be given, it not rarely happens that the labor pains go on at once rhythmically and regularly, so that the introduction of the second bag is not needed.

There is no certainty about the action of the preparation in such cases, but it occurs often enough to be worth a trial in all instances, and can be productive of no harm or annoyance.

In the second stage of labor, with the head firmly fixed and moulded through the brim of the pelvis, and in those cases where, in *multiparæ*, there is no doubt as to proper relationship between the fetal head and the pelvic brim, pituitary extract is used to increase the actual propulsive powers of the uterine muscle, and to hasten the progress of labor. The further down in the pelvis is the fetal head, the safer is the indication for the use of pituitrin, if progress be slow.

The term "atony" does not mean that the uterine

muscle may not do its work. We select a period, to be sure, when it does not, and call it uterine atony. All of us have been prompted, at times, to give morphine or other drug, let the patient have a restoring sleep, and then await, sometimes with success, sometimes not, the recurrence of forceful pains. In many other instances we have applied forceps without delay and so aided delivery. Such a uterine muscle can be made to work successfully if proper stimulation be given it. Hours of annoying pain are saved, and the use of forceps almost entirely obviated. In fact I have been using pituitary preparation in more than three-fourths of my cases, and I find the use of forceps indicated once where formerly I was compelled to use it four or five times. The use of the drug toward the end of an indolent second stage, plus the careful administration of chloroform, constitutes as advantageous and practical a form of "twilight sleep" as one could possibly wish for.

Only the other evening I was asked to come and apply forceps in a case where the head had been visible for a long time, but progress had ceased in spite of continued pains. I advised the administration of one-half ampule of pituitrin, and progress became evident almost immediately; shortly after chloroform was administered, and, with the aid of a second half ampule, delivery was successfully terminated, and a twelve-pound baby was born without the patient being aware that any change had taken place. My observations so far have been confined mainly to primiparæ. It is, however, in multiparæ that pituitrin gives the most astonishing results. Since using this drug I have not been compelled to spend more than two hours at the bedside of any multipara in labor.

Once labor pains begin, whether the head is engaged in the brim, or whether, as so often happens, the head is well above the brim, the use of this drug produces astounding results. Cases in which there is scarcely any dilatation of the cervix and no fixation of the head in the pelvic brim, deliver themselves in anywhere from fifteen minutes to two hours. Not that this happens always, but it almost constitutes the rule.

When once a hypodermic of pituitary extract has been given, it is a risky thing to leave the patient's bedside. This naturally holds true to a far, far greater degree in multiparæ, and is decidedly applicable to multiparæ in the second stage.

The method which I follow in the application of this remedy is to inject half an ampule, and observe its effect, and thereafter to inject, at intervals of half an hour and up, half an ampule of pituitrin as often as may be indicated. We judge of progress by the fewest possible examinations. The visibly contracted uterus, the character of the patient's outcry, the sensation of pressure on the rectum, the feeling as if the "bowels want to move," all give us additional information.

I can imagine no injurious effects from this procedure, and I believe that the drug has no harmful influence. I have often given six to eight injections at intervals of half an hour, each consisting of half an ampule. The effect of each of these hypodermics is generally temporary and evanescent.

It may be said, then, that in any case where the position is one that does not demand correction, where there is no malrelation in dimension between the fetal head and the bony pelvis, where the progress of labor is slow, or where it is desirable to accelerate it, or where, because of any condition in the mother or the child haste is necessary, pituitary extract is indicated as a safe and valuable aid in primiparæ or multiparæ, in normal labor or in dry labor.

In the third stage previous hypodermics have a splendid effect, leading to the ready expulsion of the placenta, and causing firm contraction of the uterus. I have used ergotole at the end of the second stage for years, and continue to use it, no matter how much pituitrin has been injected, as I find its action prompt, effectual and extremely reliable.

In the post-partum stages I occasionally use pituitary extract to aid in the involution of the uterus, but its use should not be continued for too many days, as it might well cause a marked atrophy.

So far as my experience goes, there is no contraindication, of a general nature, to the use of this remedy. It may be used in eclampsia and in those cases where the kidney is involved. Aside from its application to the stages of labor, it is of value in overcoming the atony of the bladder so frequently present on the first or second-day post-partum.

In the various stages of inevitable abortion it is of value. It is especially indicated after curettage for this condition. When repeated daily or every other day, for a long period of time, it aids in contracting the subinvoluted uterus, the fibrotic uterus, or the uterus which bleeds without definitely ascertained pathological cause, but a cause which exists in the uterine wall itself.

I use it in cesarean section, the moment the operation is begun. Just as soon as the abdominal incision is made a hypodermic of pituitary extract is given. Contraction of the uterus is already apparent after incising the uterine wall, as delivery of the fetus through the incision is somewhat difficult. After removing the placenta and membranes the uterus contracts mightily, and the uterine wound seems very small indeed. Bleeding is remarkably slight. I administer it for a week or ten days after a cesarean section.

A few words as to the "twilight sleep" of which so much is heard. I have gained the impression from the experience which I have had in the administration of morphine, narcophin, hyoscine, and scopolamine, that they inhibit and nullify the activity of pituitary extract. If this be so then the strongest criticism which can be made lies against this method of "twilight sleep." For anything which prolongs labor and interferes with a drug as valuable as pituitrin, a drug which shortens labor to such a marvellous degree, loses most of the advantages which can be claimed for it. I have yet to recall a patient who has refused to have a second or third child because the labor pains in the previous experience were too severe.

And, especially from the standpoint of the physician who takes personal care of his patient in labor, and who prefers to spend more than an occasional few minutes at the patient's bedside, the advantages of the pituitrin method, as compared with the narcophin-scopolamine procedure are certainly evident. Unless it can be absolutely proven that the use of narcophin-scopolamine does not interfere with the action of pituitrin, the use of the former implies a decided disadvantage. Were it possible to combine scopolamine and narcophin with pituitrin, and make the labor less painful—produce amnesia—and shorten its duration decidedly, then the combination would be ideal.

In closing I simply wish to state that we have in pituitary what I consider the greatest aid intro-

duced into the field of obstetrics since I have studied medicine; that its use can be highly recommended in the vast majority of cases, those cases constituting the ones in which birth per vaginam is possible without corrective procedure.

THE SIGNIFICANCE OF THE VON PIRQUET TEST.*

By THOMPSON FRAZER, M.D.,

ASHEVILLE, N. C.

Ever since 1907, when von Pirquet announced his discovery of the reaction which bears his name, this test has been charged with a great variety of interpretations and implications. Indeed, the technique of the test has so many variants and the literature on the subject has reached such amazing proportions that one is baffled by the conflicting results that have been obtained, and is tempted to discredit the importance of a procedure which is apparently so complicated and whose significance seems so obscure. It is not surprising, therefore, that the test is so infrequently applied by the profession generally. I believe, however, despite the discrepancies which exist between the results of different observers, that the von Pirquet test has a wider field of usefulness than it has been accorded.

Von Pirquet, it will be remembered, found that the reaction occurred in but a small proportion of infants, but that with advancing years it became more and more frequent, so that at the age of ten about 70 per cent of the children tested gave a positive reaction.[1] Almost no adults gave a negative reaction. The large percentage of reactions in older children without symptoms was in striking contrast to the infrequency of reactions in the first year of life, in which nearly all infants who reacted presented definite symptoms of tuberculosis. The occurrence of the reaction not only in those suffering with clinical tuberculosis, but in those apparently enjoying good health as well, at once raised the question as to the value of the test: what significance has it if the tuberculous and the well alike give a positive reaction? The significance[2] of a positive reaction is of course *not* that we are dealing with a case of tuberculosis in the usual sense; it indicates only a previous infection with tubercle bacilli. More properly it is a test for tuberculosis antibodies only, for infection might be present and the reaction negative owing to the absence of tuberculosis antibodies.

As infection with tubercle bacilli is uncommon in early life and as infection so regularly develops into clinical disease during this period it was concluded as the result of the experiments of von Pirquet that a positive reaction to the cutaneous test is of the greatest diagnostic significance during the first two years. It was believed, however, as the percentage of reacting children increased so steadily with succeeding years, that a positive reaction in the later years of childhood was an evidence of "latent" disease only. It received scant recognition, therefore, and after the age of two a negative reaction was alone considered of definite value, this being looked upon as strong presumptive evidence of freedom from tuberculosis.[3]

One does not question the figures of von Pirquet and other observers have gotten similar results. Jacob found the test positive in 30-40 per cent of village children. Since the test first came into vogue, however, our ideas as to its frequency and its meaning have suffered some changes, and as a result of more recent experiments it seems not improbable that the scope of the test may be so enlarged that not only will it be diagnostic in infancy, but it may be made to play a part in the prevention of tuberculosis; that is, of clinical tuberculosis.

The more recent figures are of interest in that the percentage of reacting children is smaller than in the series of von Pirquet. Thus Shaw and Laird[4], performing the cutaneous test on 330 children in orphan asylums found the average of positive reactions to be 28 per cent., increasing from 2½ per cent. under two years of age to 45 per cent. between 6 and 14. While Sachs,[5] experimenting on children of tuberculous parents, obtained a positive reaction in 49 per cent. between the ages of 7 and 14, reaching 60 per cent. between 15 and 20, and 73 per cent. above the age of 20. More striking are the figures recently published by Wachenheim,[6] who made the test on 100 children of the East Side of New York, the greater number of whom were of Jewish extraction. Twenty children clinically tuberculous all gave a positive reaction. The remaining 80 were all suspected of tuberculosis because of chronic cough, impairment of general nutrition, or some other suggestive sign. Although the reactions increased with age the percentage in this series is much lower than one would expect. Thus, 24 children under six gave no positive reactions, in 36 cases between 6 and 9 there was a percentage of 5.6, while 20 children of 10 years and over had only 15 per cent. reactions. While admitting the racial feature as a possible explanation for the low figures obtained, Wachenheim concludes that on the East Side at least, "most children that look tuberculous are free from the disease; their condition is due to other and less serious causes."

My own figures, because of the small number tested, have but little weight. I was surprised, however, at the infrequency of positive reactions. Thus, of 36 children tested, 8 were under 7 and were all negative. Twenty-eight between 7 and 14 gave eight reactions, or a percentage of 28.

The disparate results obtained by various observers are not easily explained, although von Pirquet admitted that his figures were probably higher than those of other cities on account of the tests having been all made on children of the poorer classes, these children being infected at an early age because of the prevalence of tuberculosis among the parents. At any rate, the frequency of infection would naturally be greater among institutional children, in hospitals, and among the poorer classes generally, especially in tuberculous families, and before we can arrive at a general estimate of infection we need data which will include all classes.

Some discrepancies must be attributed to differences in technique[7] and to lack of agreement as to what constitutes a reaction. It is unfortunate that as yet there has been no uniformity in the application of the test, or rather there have been proposed so many modifications of the original procedure, that it is not always permissible to compare the results of one observer with those of another. How far the different methods of scarifying, the depth of the abrasion, the concentration of the tuberculin used—how far these affect the results have not been definitely determined. For this reason the test should be standardized; the undiluted tuberculin should be used, and a uniform method of scarifying,

*Read at a Symposium on Tuberculosis of the Southern Medical Association in Richmond, Va., November 10, 1914.

preferably with the von Pirquet scarifier, should be employed. The skin of the forearm, after being sponged with ether, is scarified through a drop of tuberculin just sufficiently to obtain a moist pink hole without drawing blood. A drop of glycerin is used for the control. The typical reaction which begins after a variable latent period of from a few hours to several days is easily recognized, and consists of a papule usually reaching 10 millimeters (2/5 inch) in diameter, and attaining its maximum size in 48 hours, after which it decreases in size. In an intense reaction the inflammatory area may be 20 millimeters (4/5 inch) or 30 millimeters (1 1/5 inch) in diameter. In order to avoid overlooking a reaction the patient should be seen 24 and 48 hours after the test has been performed, for at times there is seen the "early" or "premature" reaction with a latent period under 24 hours, at other times a delayed or "sluggish" reaction, beginning after the lapse of 24 hours. The normal traumatic reaction shows itself only as a slight redness at the end of 24 hours, but in order to be on the safe side von Pirquet has advised that all reactions below 5 millimeters (1/5 inch) diameter be considered doubtful, and the test repeated. Petrushky regards a doubtful test as positive if on the second trial the reaction is more marked, and while some claim that a negative reaction may become positive on some subsequent repetition most authors regard a second test as final. Rivière thinks that a negative result after two attempts is a valuable proof of the absence of tuberculosis.

We are still in the dark both as to the conditions responsible for varying degrees of reaction, and as to the proper interpretation of these reactions, although it is evident that there are two factors concerned in the production of sensitiveness, "a sufficient call on the defensive mechanism, and the power of active response."[8] Thus, it has been noted by some that the more latent the tuberculosis, the more concentrated must be the tuberculin to cause a positive reaction. As the result of the employment of dilutions of tuberculin, however, it has not yet been possible to differentiate active and latent disease except to a limited degree, although it does not seem impossible that in the near future we may be able better to interpret the varying degrees of sensitiveness met with.

The power of response is a variable factor: some areas of the skin are more sensitive than others, the back more so than the arm. Again, it has been noted that during an attack of measles the reaction is negative, although tuberculosis is present, also that response to the test is absent in cases of advanced tuberculosis and when the patient is moribund. Von Pirquet says that sluggish reactions are more often encountered in older children, especially clinically unsuspected cases, and that they are seldom met with in those manifestly tuberculous. The explanation that has been offered is that an active lesion causes the specific antibodies to circulate in large quantities in the blood, combining quickly with the tuberculin, while in a latent lesion the antibodies are fewer in number and it takes longer for a sufficient number to be produced and to combine with the tuberculin introduced.[9]

We are unable, at present, to account for the differences in the character of the reactions, nor are we able to reconcile the various estimates as to the frequency of positive reactions. On one point, however, all are agreed, viz., that tuberculous infection increases with years. Stoll,[10] as a result of tests performed on a hundred odd children in orphan asylums, noted that those who gave a positive reaction were, on the average, eleven months older when admitted than those who did not react—in other words, the extra year spent in their homes increased the chance of infection. He also found that when several children from a family in which tuberculosis was known to be present were admitted, "it was almost invariably the youngest, or the one earliest removed from the home that escaped infection."

With the recognition of this increasing infection and also of the relation which exists between infection in childhood and clinical tuberculosis in later years, it follows that if we detect the presence of infection and treat the child accordingly we shall have made a great stride in the prevention of clinical tuberculosis or disease. Here then is the applicability of the cutaneous test: to detect the presence of infection at the earliest possible moment; and to this end the employment of the test annually, as advocated by von Pirquet, would contribute in no small degree.

The value of the test will vary of course at different ages. It is evident that in the very young infection can not have existed long and that as the child grows older there will be a greater number of latent infections—infections which never have caused trouble, and the majority of which, perhaps, will not be productive of symptoms in the future. Stoll thinks that "a reaction in a delicate child is a sign of grave import and means 'watch out'," while Miller and Woodruff[11] have said that although "every case reacting to the local tuberculin test does not require the same treatment as a case of tuberculosis, it should be kept under careful observation." At exactly what age the reaction ceases to have a definite value can not be said positively. Baldwin[12] thinks it of diagnostic importance up to the age of ten. "It is likely that the child should be treated, or at least watched," he says. "If no symptoms have appeared before the test is made and the test is positive, it may be said without doubt the child has not had tuberculosis long. . . . The tuberculin reaction in children, therefore, is of great value, and must not be ignored."

Wachenheim's reliance on the test is unqualified. He thinks that there is no reason to assume that in reacting cases the tuberculous infection is obsolete or even arrested and is of the opinion that "a positive reaction should be regarded as an important danger signal, as evidence that a tuberculous process is either still active, or likely to become active at any time, and never to be carelessly dismissed as a mere relic of a past and gone infection."

Such are, in brief, the views of the more recent writers. They leave little doubt in my mind as to the significance of the von Pirquet test, and while I realize that in this short paper I have only scratched the surface of the subject I believe that as an embodiment of the different points I have tried to bring out, the following conclusions are justifiable: (1) That a positive cutaneous reaction is less frequent in children than it was once thought to be, the high percentage of reactions obtained being due to the application of the test chiefly to infected children of the poorer classes and (2) that therefore a positive reaction is of greater significance than it is commonly supposed to be. (3) That while there is an increasing percentage of reactions with years, and a corresponding decrease in the value of the reaction, the view usually held

that the reaction has significance only during the first two or three years of life is not borne out by recent figures, and that we should be suspicious of a reaction occurring up to the age of ten. (4) That annual tests be instituted in the effort to detect early infection, and that, bearing in mind the fact that many if not most cases of clinical tuberculosis in later years are due to renewed activity of old foci, we should seek by proper means to prevent the development of "infection" into "disease." (5) That a negative reaction, negative on repetition of the test, is valuable evidence of the absence of tuberculosis unless the child be suffering with advanced or acute disease, especially measles. (6) That further study of the test is necessary before we can fully interpret the reactions, and that, in the future, it is possible that refinements of technique may enable us to determine with greater accuracy the recency of the infection.

THE GENERAL USE OF DISTILLED WATER,

THEREBY SECURING THE ELIMINATION OF TOXINS LEADING TO ARTERIAL CHANGES, AND THE ELIMINATION OF WATER-BORNE DISEASE.

By L. L. VON WEDEKIND,

MEDICAL INSPECTOR, U. S. NAVY, COMMANDING U. S. S. "SOLACE," HOSPITAL SHIP.

In presenting a theory to men of science, facts relative to results obtained in support of that theory are worth all the argument possible to place on paper; are convincing, interesting, and provocative of reasoning on the part of the reader, leading more rapidly to self experiment than any other means of inciting interest, and I will therefore, before discussing the subject, present facts. We have, as a class, practically accepted as an axiom, "A man is as old as his arteries," and after twenty-five years' association with the men who demonstrate this assertion to be an axiom, I have concluded to offer to you my solution of the riddle, "Why is arteriosclerosis so markedly absent among officers and men of the U. S. Navy?" and strive to convince you that this solution is axiomatic. The strength of the Navy and Marine Corps is between 65,000 and 70,000 men. The report of the surgeon-general for 1913 tabulates one death from apoplexy, and places arthritis as the least common of all diseases. Preventable diseases, typhoid, smallpox, and many others, have been eliminated, and the principal duties of a medical officer on a battleship are to sustain efficiency by commending always what leads to perfect health. That the constant use of distilled water, not only for drinking, but also for cooking purposes, absolutely eradicates the possibility of infection from water-borne disease, is a fact, and needs no argument. That the navy is typhoid proof by prophylaxis should be of extreme interest, and we are immunized for the reason that we may visit all ports in the world and on shore in infected ports, are liable, of course, to that particular infection, for really we do drink water even on shore.

In a series of observations of blood pressure on navy men aged from 40 to 60, I have yet to note anything over 142 millimeters, the average being 136, and these were taken haphazard—not selected. This, in connection with the note quoted above, is of importance and encouraging. Men new to the navy will for a period from six to nine days, and sometimes longer, discharge solids in solution in urinary excretions far in excess of what is considered normal—and thereafter the excretion will equal that of men not on distilled water—but remember that distilled water ingested with no salts in solution is discharged (as is any potable water), having in solution as much solid as has a charged water. The difference before drinking either type of water would be found after evaporation, and this is self evident. Distilled water, hungry for soluble ingredients—the natural condition of all except rain water—has its appetite satisfied in coursing through the body and removes excess, up to its capacity, until excess ceases to exist, and is ever ready to meet an emergency. In this day of ours when everyone discusses blood pressure, sclerosis, exercise, athletics, and hygiene, I think it well to touch on facts relative to blood pressure, and in non-technical terms, so that those who run may read, and to show that hope remains even when he of 40 demonstrates 155 millimeters instead of 136, as he should. Increased blood pressure (and to the man who has it, visions of hardening of the arteries, apoplexy, and paralysis) by general vasoconstriction, the result of circulating toxins due especially to defective metabolism of meats, produced by gouty and uremic conditions, and this constriction controlled entirely by the medulla (starvation or toxin irritation), is a condition so far as diagnostic importance is involved, not to be mistaken for mental or sensory nerve stimulation, both of which are temporary and unimportant. Remember that this high pressure is the forerunner of sclerosis, the cause and not the effect of the arterial degeneration, as is so plainly demonstrated by its selective location for damage, the aorta, kidneys, and liver, where the toxins not eliminated rapidly enough tire out the latter two organs and the inadequately excreted poison accumulates in the blood, and as a consequence, what more natural than that the vascular system suffers an aortitis on account of the pounding not only of impure toxic blood, but increased cardiac action due to peripheral contraction; and these conditions which have brought about this high blood pressure, if they are permitted to persist, will cause the development of changes in the vessel walls and turn a functional contraction into a structural one, diminish the arterial lumen, set up an arterial degeneration. In fact, a sclerosis is the effect rather than the cause of high pressure. So much for facts. These I consider indisputable, and

the reader may take them for what he considers them to be worth.

It has been, and is claimed, that the excess of chlorides is a cause of temporary high pressure, and now admitting this, we have the deposition of soluble salts in degenerating arterial walls, and a structural change permanent and pathological. Chlorides are interdicted in some conditions, and if to this we add copious drinking of distilled water, taken as a vehicle hungry for soluble matter, the excess is carried off—toxins are diluted and rapidly excreted, constriction of the peripheral circulation is released by feeding and reducing the medulla irritation, and equilibrium is established by removing the exciting cause of the disturbance, and is continued by continually offering the opportunity for such elimination.

A foul sewer may be rectified by flushing, by disinfection, or by both methods. A poisoned human system is treated by disinfecting it internally. Why not add a thorough flushing, and when sweetened, continue for all time to flush it—prevent repoisoning by a constant stream? I have treated gouty patients in this way, not with brilliant success, but with results satisfactory to the patient and me. The all-important point to remember is, discover high pressure when it is functional, before it becomes the result of organic disease, and I firmly believe that this may not supervene, if what I suggest is carried out, for I have had many years of opportunity to observe, and results speak for themselves.

In my extensive travels about the world I have always been impressed by the fact that the illiterate inhabitants of the tropics, even the savages, treat their sick by water ingestion. Naturally many cases receive a large overplus of the exciting cause of their illness, but the object to be obtained—"sweating"—in fevers is attained, and by the skin and kidneys the poison is simply poured out.

Accept any one theory of the etiology of rheumatic or gouty arthritis, or accept all of them; consider it an infection, a metabolic flare-up, an acid excess and deposition; or that a hormone and enzeme had a falling out—or whatever you will; the object to be obtained first, foremost, and always, is the elimination of the poison. Deluge the system with an inordinately thirsty vehicle, a liquid normally carrying solids in solution; deluge the system with a liquid as dry as a sponge, so far as the presence of soluble ingredients is concerned, and you have an ideal elimination, irrespective of the theory you may have espoused.

Blood depletion in high pressure, up to 30 ounces, is often resorted to for two reasons; the first is obvious, while the second, very frequently overlooked, reduces by just so much the toxemia—in other words, it dilutes the poison. Ingestion of large quantities of distilled water in such conditions reduces permanently a high blood pressure, simply by diluting a concentrated poison, excreting it rapidly, feeding the medulla, permitting unimpeded peripheral circulation, and affording a rest to kidney and liver, by delivering weakened solutions for smelting purposes.

Understand, I am not offering this as a treatment for a disease condition. I am urging strongly that the rest of the world lives as do we, some 70,000 strong, using distilled water for cooking and drinking, and live on and on, youths at 65. We do not develop arterial degeneration, gout, and rheumatism, though not surrounded by home comforts, regular seasons, regular amusements, and home life. Our men wash their own clothes, they wash their home each morning, instead of sweeping it; they are wet some portion of each day, and frequently a good portion of the day; are in tropic heat and liable to have midwinter within a week; work strenuously, hard, and constantly.

Overfeeding is a habit, nothing more. Overdrinking of water may become one; agreeable, constant, and productive of such visible results as to be compellingly convincing.

Efficiency, efficiency, is the cry of the times. The duties of a U. S. naval officer are all centered in obtaining the highest efficiency value of his men, and the medical officer advises always with this one object in view. Preventable disease no longer exists in the service, and though we do not claim to have introduced distilled water—that was necessary with the growth and advancement of the navy—we do claim, as naval surgeons, to know more of its benefits, effects, and possibilities than any other men in the world, for we only of the naval profession live, move, and have our being with distilled water—and, *nota bene*, and that is all we get.

To those whose homes have been devastated by water-borne disease, boiling water is now routine; to such I suggest distill it, and prevent other troubles. To those who have not experienced the harrowing anguish of a "stroke" in "Dad," hurry up and pump him full of distilled water, and you'll never know what harrowing anguish means, and he'll really live to call you blessed. Form a habit of drinking distilled water. It is pleasant, invigorating, rejuvenating. Make it a point to take three glasses a day in excess of your desire, and you will very soon appreciate the reason why life insurance companies assert that, "Eliminate the hazards of a naval officer, and he is the best risk in the world." The real function of a physician today is the prevention of disease; he can fulfil his destiny only by keeping his eyes open, investigating cause, recognizing effect, and casting his bread upon the waters. Incidentally, may I venture to say when you read of deaths from heart disease, kidney trouble, acute indigestion, aneurysm, and allied affections, that all of them could have and would have been prevented had the unfortunate been lucky enough to have been in the navy, unknowingly preventing the development of the trouble which killed him, and also, to say that in time, disease will be entirely eradicated, without being accused of inferring that disease is not material? I had amebic dysentery for seven years—that is the answer.

To convince the laity is as impossible as it is to forecast the settlement of the Mexican question. Anticipating the assertion of the well-meaning clergy that if God wanted us to drink distilled water He would have made water without soluble salts, I'll answer, we take too much condiment; now I'll have to qualify that by saying very much too much. To the antivaccinationist, the Christian Scientist, and all the other "ists," material or non-material, that we have 70,000 men, hale, hearty, robust youths who at sixty-two equal the "ists" at thirty-five, and that is the answer. To the suffragette—who seeks votes and youth eternal—well she knows; you don't have to argue! In any home—in fact, in all homes—the inventive genius in the person of "Dad" or any of the boys, given a tea kettle, a copper coil, a piece of rubber tubing, a bucket of cold water, and a glass preserve jar, or ordinary water pitcher, and in half an hour you'll have a still big enough

to furnish water for drinking purposes. But for goodness sake don't put the ice man's ice into the water, and don't in your suddenly awakened enthusiasm buy distilled water from your druggist. He has a well-labeled bottle, but that's all. Let George do it, at home, until you can buy one that will produce about 20 gallons a day—save life, suffering, loss of time, money, and last but not least, that harrowing anguish which newspapers speak of, and which I mentioned. Stills can surely be constructed to burn wood, coal, oil, gas, garbage, dust and dirt—anything containing thermal units. The cost? Compare it with that of doctors, nurses, medicines, and then think.

De Leon's "Spring of Eternal Youth" lies not hidden in Florida, but it bubbles always from the aseptic nozzle of the chilled scuttle-butt of an American battleship.

REASONS FOR DISCREPANCIES IN REPORTS ON THE WASSERMANN REACTION, FROM A TECHNICIAN'S SIDE.

By M. F. SCHLESINGER, A.B., Ph.G.,
NEW YORK.

THERE frequently appear in the medical journals articles referring to the difference in reports of the various technicians as to the results of the Wassermann test. Because of these differences, clinicians lose confidence in this important test which aids so materially in the diagnosis and treatment of syphilis.

These conflicting results can be attributed to several sources which I shall try to point out, and also show the way they can be avoided. One road to error is the desire on the part of the serologist to improve on established and proven methods—another is indifference and carelessness in entrusting to subordinates important minor details necessary to the proper conducting of the test.

It is unfortunately too true that many laboratories want to improve on the Wassermann test as given out by Wassermann, Bruck, and those who have otherwise succeeded in making the test fairly reliable. In this, as in so many other problems, the pupil deludes himself with the idea that he can successfully elaborate on the teachings of the master.

The Wassermann reaction is based upon the observation that syphilitic blood serum in the presence of certain lipoids will bind complement to such an extent that upon the subsequent addition of hemolytic amboceptor and corresponding corpuscles hemolysis will be prevented to a greater or less extent. In non-syphilitic blood, hemolysis is complete. In spite of numerous investigations, the exact interpretation of its physiologico-chemical significance is as yet an open question.

The phenomena might be explained upon the basis of the physical absorption of complement by the reaction product of the lipoid substance present in the organ extracts—preferably the heart and the liver—and as yet unknown component of syphilitic blood serum.

The technique of Wassermann and Bruck, if properly and conscientiously conducted, can be depended upon to show positive results as follows: Primary syphilis, 84 per cent.; secondary syphilis, 91 per cent.; tertiary syphilis, 81 per cent.; hereditary syphilis, 100 per cent. These are my figures based on histories given to me after reports were rendered, and not before. I am indebted to Dr. Victor C. Pedersen for many of the cases and histories.

In order to improve on the accepted scientific method laid down for us, some technicians adopt "modifications." These are generally labeled "my modifications," and resolve themselves into nothing else as a rule than time savers and trouble savers—quick results in less time with less trouble—and are not for the purpose of serving the clinician, but to simplify the test for themselves. These time and trouble savers suggest the use of manufactured stock preparations, and the material used for making the Wassermann test, which should be prepared under the personal supervision of the technician, is bought in the form of bibulous papers saturated with amboceptor, etc. Others again, who take particular pride in showing a greater percentage of positives, adopt modifications in antigen, suggesting the addition of cholesterin and chemicals. These are "short cuts," but they lead to nought else than error and failure.

The laboratory worker is certainly justified in adopting ways and means to arrive at best results in the shortest period of time, but not when accuracy must be sacrificed. In working the Wassermann test, time saving and labor saving devices must have no part. In order to make a careful and conscientious test, at least six hours of work must be devoted to every series.

Carelessness in the preparation necessary before the test is another prolific source of error. As a rule these preparations are left to the diener and subordinates, the technician putting in the final touches only, using the so called "personal equation" in interpreting results. It is true personal equation must enter into the work, but this from the very starting of the test by close attention to the minor, but important details of preparation and testing of materials, etc., and not, as is frequently the case, simply the reading of the tubes and a comparison of the history of the case as given by the physician and trying to make the findings conform to this.

The laboratory is not to be furnished with a history of the case—that is of no concern to the technician; he is to make the test with the material at hand, and if he has sufficient ability to make the test right, to report his own findings.

The technician, if he is to be biased either way, is to protect the non-luetic individual from a wrong diagnosis and useless treatment. Surely less harm can result from a negative report in actual syphilis than that a positive result be saddled on a non-syphilitic patient with its trying treatment and mental distress.

As mentioned above another source of erroneous reports is indifference to the many little details which require the personal attention of the technician himself, such as titrating the hemolytic amboceptor and the complementary value of the guinea-pig serum.

One text book mentions that barometric changes have an influence on the hemolytic amboceptor, and that the test should be made only on dry, crisp days in preference to humid weather. Where the work must be done every day regardless of atmospheric conditions, this is not practical—furthermore, it is unimportant. I have found that it is the complement that varies, and not so much the amboceptor. Accordingly, even though the hemolytic amboceptor is titrated and a definite strength is ascertained at the time the amboceptor is made,

it is nevertheless necessary before beginning the test to titrate the amboceptor out against the complement each time. The complement varies on warm days, changing so rapidly that it may become inert on the working table and between tests. Hence, the necessity of keeping the complement in the ice chest when not in actual use—furthermore, it should not be used after it is twelve hours old. In fact, all materials employed should be kept in the ice chest.

The complementary value of the guinea-pig serum also calls for attention—hence, the feeding of the animal is a detail that must be looked after. In guinea pigs fed exclusively on cabbage leaves, the serum has little or no complementary value—when oats are fed, the complementary value is raised materially, sometimes to the extent of four or five times. From this it is clear that the animal must be fed on a mixture of cabbage, carrots, oats, grain, etc.

I am convinced that because of the inactivity of complement, a great number of negative cases are reported as positive, and thus many non-syphilitic patients are being treated for syphilis. If controls are employed and material titrated this can be avoided.

Occasionally cases are met with that show a decided fixation of complement one day and no fixation the next. Sera of this kind are spoken of as "paradox sera," and are fortunately rare. This is explained by the assumption that such sera contain minimal quantities of antibodies which may be sufficiently large to give a reaction at times, and then drop in content to such a degree as not to be detected by the reaction.

In reporting results of the reaction, most serologists employ plus signs thus (+) (++) (+++) (++++) to indicate the degrees of inhibition of hemolysis, and this is preferable to merely positive or negative.

Treatment has a material effect on the reaction and it is of some encouragement to the luetic patient to note the decrease in the plus signs as treatment progresses until it becomes negative.

I have found that in order to get accurate results, the following must be strictly adhered to:

Patient's Serum.—In order to exclude the positive results obtained in certain cases of cancer, nephritis, scarlet fever, leprosy, sleeping sickness and tuberculosis, the patient's serum must be heated for half an hour at 56° C. (inactivation) the syphilitic antibody alone being thermostable. The thermostability of the serum of inherited syphilis is the highest.

The Antigen.—The opalescent (lipoid emulsion) working antigen should be made up fresh on the day of preparing the test. That prepared from the organ is far more reliable than that prepared from bile salts and cholestrinized extracts. Antigen should be titrated at least every five days.

Complement.—The complement should be obtained from guinea pigs carefully fed. The animal must be killed the same day that the test is to be made and to be kept on the ice. It must be carefully titrated and adjusted to the hemolytic amboceptor to be used.

Hemolytic Amboceptor.—The titer of the amboceptor should be at least such that 0,5 c.c. of a 1:2000 dilution will completely hemolyze 0.5 c.c. of a 5 per cent. suspension of washed sheep's cells in the presence of 0.5 c.c. of a 1 to 10 dilution of guinea pig complement within thirty minutes at 37° C.

The Washed Corpuscles.—Sheep cells should be as fresh as possible and should not be used if there be any discoloration from standing. It is a practice to add formalin for preserving, where the laboratory is remote from a slaughter house. Formalized sheep cells may prevent hemolysis and prove a cause of error.

THIRD AVENUE AND TENTH STREET.

ENORMOUS TUMOR OF THE UTERUS.

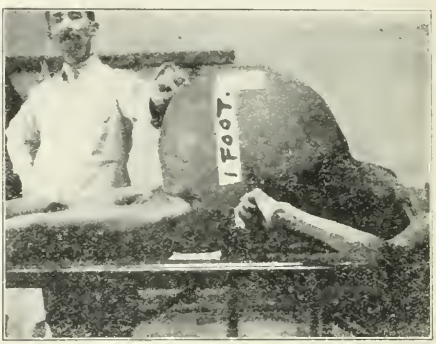
BY ORLANDO H. PETTY, M.D.,

AND

ROBERT L. PITFIELD, M.D.

GERMANTOWN HOSPITAL, PHILADELPHIA.

AN ignorant negress, R. B., widow, aged 54 years, was admitted to the wards of the Germantown Hospital suffering from a large abdominal tumor. She could give very little history of herself and was indeed so weak and ill from an iliocolitis which she had had for two months that the meagre data which she was able to give was of little value. The only manifestation of fecundity was a pregnancy which terminated in an early abortion. For seventeen years her abdomen had been enlarging and at one time an attempt had been made to relieve her of this abnormality, but the wound was closed and the tumor remained behind.



Physical examination showed a weak, frail, exhausted woman. She was emaciated and bedfast and she said that she had been so for two months. The tumor was a huge globular mass, measuring forty-eight inches around in the plane parallel to the long axis of the body and fifty-two inches around the umbilicus. The tumor fluctuated freely and the skin showed an old scar and enlarged veins coursing over it. So great was the mass of the tumor that the patient was unable to lie on her back without having it supported by a nurse. Until two months ago she was able to get about her house.

She became rapidly exhausted and the tumor grew very cold to the touch. To maintain the body heat in such a liquid mass devoid of blood vessels no doubt was too great a task for her circulation, and death appeared to be due to exhaustion.

With at least some palliative surgical measures for relief within a mile of her home it is a marvel that such a pathological condition should exist in a medical center for so long.

Pathological Examination.—Chest thirty-three inches in circumference; below chest is an enormous tumor, which, including the torso, is fifty-three inches in diameter. Body not edematous. Left leg markedly edematous. Left lung completely collapsed and airless chest cavity being filled with clear liquid. Right lung adherent and seat of fibrous phthisis. Aorta normal and elastic, although heart shows advanced fibrous myocarditis, no valve lesions. Left kidney large pelvic abscess; right kidney riddled with small abscesses. The enormous tumor of the uterus, which weighed ninety-two pounds and contained seven and one-half gallons of grayish-brown turbid fluid, was adherent to the ovaries and bladder.

Microscopic Diagnosis of Tumor.—Fibromyoma with central cystic degeneration.

PEMPHIGUS FOLIACEUS NEONATORUM.

By A. L. HENKIN, M.D.,

BROOKLYN, N. Y.

THE following case, on account of its rarity and the great extent of the lesions, seems worthy of permanent record:

The child was delivered by me on October 2; female; normal birth, except for the prolonged second stage, due to diastasis recti, which required one dose of pituitrin. The child weighed six pounds and two ounces. On the sixth day the umbilical stump separated.

The next day my attention was called to a "blister" on the abdomen near the umbilicus. My examination revealed one bulla on the abdomen half an inch to the left of the umbilicus, the size of a finger nail. The bulla was flaccid, with opaque fluid contents, the fluid changing its position with the position of the child, seeking the most dependent part. There were no signs of inflammation. The temperature was 98.6°. The next day this bulla had increased in size to an area of about 2 inches long and 1 inch wide. I prescribed Unna's paste of zinc oxide, chalk, lime-water, and linseed oil. The child was very restless that night.

The following day this patch had extended to the right and to the left, involving an area covering almost the entire abdomen. On attempting to remove the dead cutis the entire skin came off with it as a single cast. It also came off from the perineum, extending to the vagina and rectum. One could easily have removed the epidermis of the entire body. There was no serum or redness underneath, except over that portion of abdomen around the umbilicus, where the surface was red and weeping, looking like eczema rubrum. Similar condition was found around the mouth, involving the lips, nose, and cheeks. Temperature was 98.6°. The mucous membrane of the mouth looked pale and somewhat raised from the underlying structure.

At 6 P. M. the temperature was 103.6°. The entire body presented a horrible picture. It looked like a raw, red, weeping surface covered with serum. The general condition of the child was very poor, showing signs of failing circulation and septic absorption. The area around the umbilicus was gangrenous.

There was no history of syphilis or tuberculosis in the family, or any similar condition. One child in the family had an eruption on the face and hands which it contracted from another child and which appeared to be an impetigo contagiosa.

355 STOCKTON STREET.

Medicolegal Notes.

Malpractice—Emergency Cases—Questions for Jury.—Action was brought for malpractice while treating a patient for a gunshot wound in the calf of the right leg. The negligence with which the doctor was charged was: First, a failure to ligate the severed and injured arteries, whereby the patient bled to death; second, in failing to visit and attend to the patient as often and as much as he should have done. The defense made to these charges was that the treatment was proper under the circumstances; that the patient was suffering from shock and loss of blood, and that had a thorough examination been made as to the condition of the arteries the patient would have died while the examination was being made. It was insisted in the defendant's behalf that in any event the case came within the class of cases known as emergency cases, wherein if a physician exercises his best judgment as to the treatment he is not liable for negligence for an error of judgment in following one treatment rather than another.

The difficulty the court had in applying this rule to the case in hand was the claim of the plaintiff that the doctor failed to make such investigation as was necessary to determine what ought to be done. This exception to the ordinary rule of negligence is based upon the assumption that the physician has informed himself of the existing conditions. Without a knowledge of these he has not proper basis upon which he can exercise his discretion. One of the complaints, and the one most strenuously insisted upon by the physician, was the failure of the doctor to inform himself as to whether the arteries were cut off or punctured. The doctor admitted that he did not ascertain these things, and it was shown by expert witnesses that he should have done so; that he should have found the bleeding point and stopped it. After he determined what course to pursue without this information he was in no position, as a matter of law, to invoke the protection of the rule in emergency cases. It was argued that this information could not have been obtained without endangering the life of the patient. That question was in dispute and was one of the points on which there was a conflict of expert testimony. It was therefore properly submitted to the jury to determine whether he did what was necessary to bring his treatment within the rule in emergency cases as well as whether he gave the patient the attention and care which the case demanded. It was held that the testimony on both questions was such that the jury would have been justified in finding either way, and therefore their verdict for the plaintiff was not disturbed.—Dailey vs. Shaffer, Michigan Supreme Court, 146 N. W. 192.

Malpractice—Potts' Fracture—Burden of Proof.—Action was brought for malpractice in the treatment of a severe Potts' fracture of the left foot. Owing to the swelling of the joint and an abrasion of the skin, the defendant did not invert the foot for fear of gangrene. The swelled condition, under the treatment given, continued from the date of the accident, January 23, till February 13 before beginning to abate, and the joint healed without an inversion of the foot. The trial court ordered a nonsuit on the ground that the plaintiff failed to show that the treatment given him was not proper as applied to the kind and degree of fracture he was suffering from and the conditions that developed. The evidence showed that the fracture was a very severe one, in which the fibula was splintered and the ligaments of the ankle joint ruptured; that the foot was very much swelled and discolored, and the skin partly abraded in places at the time of the first treatment. The plaintiff's counsel claimed that since the evidence showed that the conditions testified to by the defendant do not usually obtain in ordinary Potts' fractures for so long a time, the jury had a right to find that they did not in the instant case. Hence, since it was shown that in cases of ordinary Potts' fractures the danger of gangrene was usually passed in from seven to ten days, and since bony union does not take place until the third week, the jury might find malpractice from failure to invert the foot after danger of gangrene had passed and before bony union took place. All agreed that there should be no inversion of the foot until danger of gangrene had passed. It was held that the plaintiff's fracture not being an ordinary Potts' fracture, but a severe and complicated one, there was nothing inherently or obviously incredible about the defendant's testimony as to the conditions found the first day he examined the foot, or as to their continuance for the length of time shown. The trial court, therefore, properly held that such conditions must be accepted as verities, since there was no evidence to the contrary. Another claim made was that the evidence of the defendant showed that he was ignorant of the practice of inverting the foot in cases of Potts' fracture, and therefore did not do it in this case. It was held that, conceding that this was true, still, if the treatment he gave was the proper one under the conditions existing, his ignorance became immaterial. The plaintiff failed to show that a condition warranting inversion existed at any time, owing to the fact that the evidence showed that danger from gangrene continued till bony union took place, and that thereafter it was not good practice to invert. Judgment for the defendant was affirmed.—Marchand v. Bellin, Wisconsin Supreme Court, 147 N. W. 1033.

Declarations of Injured Person to Physician.—Where the amount which the plaintiff is entitled to recover depends to a large extent upon the testimony of medical experts, the Illinois Appellate Court holds that it is important that rules of evidence respecting such testimony be observed. A physician who made an examination of an injured person solely for the purpose of testifying as an expert at the trial, is not permitted to testify to statements made to him by the injured person, or in his presence during such examination, nor can he base an opinion upon such statements. Where the defendant claimed that the ailments complained of by the plaintiff were due to other causes than the accident, error in admitting declarations of the person injured to a physician who is making an examination the results of which shall form the basis of testimony at the trial and not for the purpose of treatment, is not harmless.—Kendall v. Chicago Railway Co., 185 Ill. App. 145.

New York, January 9, 1915.

THE CAMPAIGN OF EDUCATION.

AT the recent meeting of the American Public Health Association in Jacksonville a discussion took place as to whether or not cancer is greatly on the increase. Mr. Hoffman, statistician of the Prudential Insurance Company, who is the leader in this country of those who believe cancer is on the increase, rehearsed the arguments previously presented in support of his views and defended the accuracy of American mortality statistics upon which he largely bases his belief. Professor Willcox of Cornell University, on the other hand, held that probably most and possibly all of the increase in the death rate from cancer is not a real increase at all but only an apparent one. As we said in a former discussion of this subject (MEDICAL RECORD, August 15, 1914), the statistical evidence is too imperfect as yet to warrant the drawing of any definite conclusions. American statistics are notoriously incomplete and even in the registration districts we have little guarantee of their accuracy. In New York City, where the certification of marriages, births, and deaths is supposed to be perfect, the Health Department is even yet discovering delinquents and bringing them to court for punishment. If this can happen in a city under the eyes of vigilant health officials, one who would deny its possibility in other places, where physicians have not been trained to see the value of statistics and where they are under but slight compulsion to report their cases, must be an incurable optimist or rash of statement. In other countries, where more or less accurate statistics are available, students of this subject do not find an enormous increase in cancer; they admit some increase, but not much more than could be explained by the fact that more people now live to reach the cancer age.

This discussion would be more or less academic and of little importance to the world at large or even to the medical world, were it not that the advocates of the so-called campaign of education of the laity base their arguments for its necessity upon the alleged alarming increase in the prevalence of cancer. It is very right and proper that the general public should be warned of danger when it exists and should be instructed to detect the peril in its incipiency, but this does not mean that we should make a hypochondriac of every woman over 35. Every pimple on the breast or every stitch of pain in or under the gland does not mean cancer, nor does every slight discharge in a woman at or just past the menopause, nor again does a spell of heartburn in a man of 50. It is well that the physician should be consulted in the case of any unusual swelling or discharge or pain or other abnormal and persistent symptom, but it is ill that the man or woman should suffer an agony of apprehension whenever such symptom presents itself, for the chances are that it is insignificant and will pass away, as countless others have done in the course of the person's life without evil consequences. It is questionable whether the agony of mind which the fear of cancer aroused by such a campaign causes can be compensated for by the longer lease of life which is occasionally secured by a very early operation. The campaign, to be effective of the greatest good to the greatest number, should be along the line of rational argument as to the fitness of consulting the physician when anything seems to be wrong, and not by scaring the patient into doing the proper thing when it is by no means proven that cancer is enormously on the increase or that every growth or abnormality of function is "precancerous."

The campaign is, we believe, started in the wrong direction; it is the physician and not the layman or laywoman who should first be instructed. As Bainbridge says, in his excellent work on "The Cancer Problem,"* recently published, "The campaign of education concerning cancer, to be rational and safe, must be made to apply first to the general body of the medical profession, and, through the profession, to the public at large. It must have for one of its objects the maintenance, upon the part of the physician, of a standard of ethics which insures the best interest of the patient, regardless of operative and mortality statistics; and the development, upon the part of the patient, of a spirit of confidence in and cooperation with the physician. It should be aimed at health rather than disease; at physiology rather than at pathology. It must be directed toward the prevention of cancer by the maintenance of the general health, as well as toward the eradication of the various factors, within and without the body, which are thought to exercise a predisposing influence in the initiation of malignant disease."

REPORT OF THE SURGEON GENERAL OF THE UNITED STATES ARMY.

THE annual report of the Surgeon General of the U. S. Army for the calendar year 1913 is a satisfactory document. The admission rate was the lowest on record, showing a reduction over the previous year of more than 18 per cent. As is pointed out in the report the constantly noneffective rate is the true index of the loss of efficiency of the army from disease and injury. The rate indicates the average number of men in each 1,000 incapacitated for duty each day during the year. For the American army in 1913 the rate was 23.97, the lowest rate recorded. Comparing the non-effective rate for disease only for troops

*"The Cancer Problem," by William Seaman Bainbridge, M.D. New York: The Macmillan Company, 1914.

in the United States, 13.61, with the best previous rate of the army, which was 25.23 in 1896, it is observed that there was a reduction of over 2.6 per cent. The death rate was slightly higher than for the previous year, the increase being due to the accident to the coast artillery companies, wrecked while traveling at Burrow's Creek, Miss., Oct. 19, 1913, with 17 deaths.

Perhaps the most encouraging part of the report is that which refers to typhoid fever. Only three cases of this disease occurred during the year under review in the army stationed in the United States. In the army in 1912 there were 18 cases with 3 deaths; in 1911, 44 cases with 6 deaths; in 1910, 142 cases with 10 deaths; and in 1909, when the typhoid prophylaxis was first begun voluntarily, 173 cases with 16 deaths. With regard to antityphoid inoculation the report points out the remarkable decrease in admission and death rates of the enlisted men of the army in the United States as a result of the use of the typhoid prophylactic. The report goes on to say that it is to be especially emphasized that there has been no lessening of the efforts of the army to prevent, by improved sanitary measures, the occurrence of typhoid infection. Advances in the other sanitary measures have gone on, hand in hand, with the extension of the typhoid prophylaxis. It is believed that the typhoid prophylaxis is as potent a preventive against typhoid as vaccination is against smallpox. But though vaccination is a reliable measure for the prevention of smallpox, few would advocate the abolition of other needful sanitary measures. With respect to the duration of the immunity conferred by antityphoid inoculation, it is stated that while such duration is unknown, it is improbable that it is as long as that conferred by vaccine against smallpox, and therefore reimmunization at the beginning of each enlistment is believed to be appropriate, as it is also very convenient from an administration point.

The admission rate for tuberculosis was low. Venereal diseases have largely decreased among the soldiers, a result partly due to the campaign of education relative to venereal disease which has been carried on in the army for several years and which has been greatly assisted by the Act of Congress stopping the pay of those incapacitated by the disease. The rate for alcoholism was the lowest ever recorded. The rates for malarial fever were the lowest since the year 1898, at which time United States troops were first permanently stationed in the tropics.

Regarding the urgent needs of the Department, the surgeon general draws attention to the fact that the reorganization of the hospital corps is essential, if its efficiency is to be preserved. He further calls notice to the shortage of mobile sanitary units and says that in view of the great battle losses to be expected in modern wars, it is a serious responsibility to rely upon improvised units that must serve at the front. Lastly it is pointed out that the medical corps is the only portion of the army not included in the plan of education of the army instituted when Senator Root was Secretary of War.

CLINICAL SIGNS OF FRACTURE INTO OR NEAR JOINTS.

Fractures around joints are sometimes especially difficult to diagnose and this is particularly true if the fragment is small and the patient is not seen until some hours after the receipt of the injury. The diagnosis usually rests between sprain and fracture, and when the patient is first seen most or all of the so-called classical signs of fracture may be absent. In this connection a paper by W. G. Stern, read before the Section on Orthopedic Surgery in June and entitled: "The three cardinal clinical signs of fracture into or near joints" (*Jour. A.M.A.*, Dec. 12, 1914) deserves comment for several reasons.

First, we desire to emphasize one of the early points made in this paper, namely, that roentgenologists have found that at least 90 per cent. of the cases sent to them with the diagnosis of sprain are really fractures; but we take issue with the author when he implies that the blame for this state of affairs rests with the general surgeon. This is implied in the following quotation: "While the general surgeons, through whose teaching the practitioners have learned to depend solely on the presence of crepitus, preternatural mobility, and loss of function for their ability to make a diagnosis of fracture" etc. His impeachment of the surgeons would be just if that were really all they knew, but they rely on many other points including the three cardinal clinical signs of fracture into or near joints, which are now grouped as a diagnostic triad by Stern. The surgeon can hardly be blamed, however, if his teachings have not been accepted by a certain percentage of general practitioners.

What are these three signs that surgeons are charged with neglecting and which Stern presents as something new? He says the following symptoms are always present in the traumatic fractures of healthy bones and offers them as sufficient for a diagnosis, even when present alone, without any or all of the usual classical signs: (1) Localized bone tenderness over the fracture point or "pencil" tenderness. (2) Swelling, beginning at and spreading from the seat of fracture. (3) Bloody discoloration, or ecchymosis, spreading from this vicinity. We do not recognize here anything original with the author quoted but rather points which have been referred to time and again in text-books on surgery. Ecchymosis is mentioned in this connection in treatises on surgery dating back more than forty years, while localized bone tenderness and swelling were recognized as among the symptoms long before Sir Astley Cooper wrote his first book on fractures.

But while it is a fact that all these symptoms have long been recognized, the author does well to call attention again to their value, especially in connection with injuries near the joints. In vertical fissure fractures of the shaft of the tibia these same symptoms are invariably present, but it is usually of comparatively little moment, so far as ultimate cure is concerned, whether the leg be splinted, massaged, or let alone altogether. In wrist fractures, however, such as that of the sca-

phoid, the general practitioner's mistakes may bring about a disastrous result. Here the lack of proper treatment often results in severe impairment of function, for there is sometimes a wicked, persistent pain and marked limitation of extension, a very serious matter for those the following of whose usual occupation requires a supple wrist.

Swelling is of very limited value as a differential diagnostic symptom unless distinctly localized and at a sufficient distance from a joint, for effusion takes place rapidly in cases of simple sprains which are proven to be such by stereoscopic *x*-ray plates as well as by their clinical course. Point or line tenderness and late appearing ecchymosis, however, are symptoms of practically pathognomonic significance, and Stern's estimate of their value is sound.

Finally, there are several of his concluding comments with which we are in full accord and which we believe cannot be too strongly emphasized. These are: "Granted that crepitus is not essential in making the diagnosis of fracture, violent attempts to elicit the same are unjustifiable as well as brutal." "Every suspected fracture should be roentgenographed." "The old adage 'a sprain is worse than a break' is based on faulty diagnosis and subsequent lack of proper treatment."

POVERTY AND TUBERCULOSIS.

The successful treatment of tuberculosis in any circumstances is difficult, and when the disease goes hand in hand with poverty the difficulties are greatly enhanced. Can pulmonary tuberculosis be treated at home, so that the sufferer therefrom will benefit, and at the same time he will not be a menace to the immediate community? The New York Association for Improving the Condition of the Poor, during the past two years has been making an experiment in this direction and has published recently a report setting forth the results of its work. The plan of procedure thought out and put into execution by the association was to provide apartments for the sufferer from tuberculosis and his family in a building occupied solely by those in a like condition. For example, the Association Home Hospital, situated in a healthy locality, occupies two entire sections of the East River Homes. Two open staircases lead to the forty-eight apartments, consisting of from two to four rooms each, including one or more bedrooms with open air sleeping balconies. No expense has been spared to provide a maximum amount of sunlight and ventilation for each room and to render the conditions as healthy as possible.

In selecting families to participate in this experiment, preference has been given: (1) To families in which poverty and tuberculosis are more or less incipient; (2) to families believed to possess sufficient intelligence to cooperate in the experiment; (3) to families in which dependency is due to tuberculosis of the wage earner, and (4) to families in which the mother is tuberculous—in general, to poor families of any nationality and religion made or kept dependent by tuberculosis and in which there is a reasonable hope of restoring the patient to health and to at least partial earning capacity.

The report calls attention particularly to the fact that treatment is provided in this way for children too young to be admitted to preventoria, for patients unwilling or unable to leave their families, and especially for the largest, and because of its irresponsibility most dangerous class of sufferers, namely, the more or less chronic second stage but able-to-get-about cases, almost entirely unprovided for by other institutions. The supervision is so careful that although the family is permitted and helped to live a normal home life, every precaution is taken to prevent infection of the healthy members of the household.

The advantages claimed for this method are: (1) The directness of its attack upon the home conditions as a crucial, underlying cause of tuberculosis and of consequent poverty; (2) the readiness with which unsuspected, incipient cases may be detected and checked; (3) the exceptional opportunity it affords for adequate control of disease in the family; (4) its avoidance of the opposition, deterrent influence, worry, and other hardships inevitably occasioned by the separation of the sick from the well members of the family; (5) its preservation of the integrity of the home; (6) its care of classes of patients who either could not or would not go to institutions; (7) its fostering an increase of the earning capacity of the wage earner and a gradual return to normal conditions; (8) its provision against a return of either the patient or family to the inimical environment in which the disease was contracted and is likely to recur, and (9) in its care not only for the physical but for the economic and social ills, not merely of the patient but of the entire family.

It remains to be said that a perusal of the report justifies the expression of opinion that the experiment has been so far successful. Any measures whereby the lot of the poor consumptive can be ameliorated are worthy of trial, and the home hospital mode of treatment would appear to be beneficial to the sufferer, to the family, and the community at large.

Scarlatina and Salvarsan.

Scarlatina is a most treacherous affection, and even in sporadic form may make short work of the patient, even when the latter is an adult and moreover one who has been exposed to it with impunity for years. To meet the indications in such cases we have never had any remedy of value. Lenzmann was the first or one of the first to use salvarsan for this purpose and his example has been followed by numerous clinicians. At a meeting of the Rheinischwestfalische Gesellschaft für innere Medizin und Nervenherlkunde (*Muenchener medizinische Wochenschrift, October* 27), he gives the status of the subject to date. To qualify for salvarsan a patient should have a temperature of 40° C. (104° F.) and upwards, a fiery rash, severest angina, and great prostration. This syndrome represents the mildest eligible cases. Over and above these belong the cases admitted with sopor, those with cardiogenous cyanosis, those with hemorrhage, etc. The author has treated 47 cases of this severity and has lost but two. One patient died of

scarlatina fulminans. When admitted he was comatose, with the highest type of heart failure. His rash was cyanotic. Such a patient could have been influenced favorably by no plan of treatment. The other patient, aged 5, died of streptococcus sepsis which followed necrotic angina and a great plaque of hard cervical lymph nodes. The 45 recovered cases developed no complications save two with otitis media. This immunity in connection with the severe type of the disease causes one to share the belief of the author that salvarsan exerted a marked prophylactic influence. Salvarsan in these cases seems to aid as a causal remedy, which antagonizes the fever, restlessness, and angina. The temperature increases at first, then diminishes rapidly. The author believes that by antagonizing the angina, salvarsan becomes able to decrease the severity of all symptoms which are due to angina, and these make up the majority of all the symptoms.

News of the Week.

For Relief of Belgian Physicians.—The treasurer of the Committee of American Physicians for the Relief of the Belgian Profession reports the following contributions received during the two weeks ending January 2:

Union Trust Company, Sterrett & Acheson, Attorneys.		Banking Facilities Professional Services	
F. O.	$25,00	M. C. S.	$5.00

Death of Professor van Gehuchten.—On December 9 Professor van Gehuchten of the medical faculty of the University of Louvain died at Cambridge, England, where he had been welcomed after the ruin of his university and his home and the loss of his library and collection of neuro-anatomical and neuro-pathological specimens. The death of this great neurologist adds one more to the tragedies of the war.

New York's Lowest Death Rate and Highest Birth Rate.—According to the Health Department figures, the year 1914 marked the lowest death rate ever attained in the City of New York, and definitely placed this city among the most healthful of the large cities of the world. The number of deaths reported during the year was 74,803, with a rate of 13.40 per 1,000 of the population as against 73,902 deaths and a rate of 13.76 for the year 1913. Thus there has been a decrease in the death rate of .36 of a point, which is equivalent to saying that if the death rate of 1913 had prevailed during the past year 2,010 more deaths would have been recorded than actually took place. The most noteworthy feature of the decreased mortality was the splendid record in infant mortality, only 95 infants dying out of every 1,000 born. This is the lowest infant death rate attained in the city of New York, the infant death rate in 1913 having been 102 per 1,000 births.

The year 1914 also witnessed the greatest number of births that ever occurred in the history of the city of New York, there having been 149,647 children born during last year, an increase of 5,513 births over 1913.

More American Surgeons for Europe.—A number of surgeons sailed on December 30 for hospital work in France. Among them were Drs. George W. Crile, W. T. Crozier, Samuel L. Ledbetter, Tiger, Stone, Strong, and Hoffman. With them went an anesthetist from the Lakeside Hospital, Cleveland and a number of nurses. Two more Red Cross surgeons Drs. W. J. Crookson of Pittsburgh and Harry T. Lay of Montgomery, Ala., sailed last week for Genoa whence they will go to join the staff at Budapest. Dr. William J. White has announced that the University of Pennsylvania will soon send several surgeons to join the staff of the American Ambulance Hospital at Neuilly, Paris.

A Floating Hospital for Deep-Sea Fishermen.—The revenue cutter *Androscoggin* sailed recently for the coast of Nova Scotia where she will be put in service as a hospital ship for the American fishermen. She is fitted with a large sick bay and is stocked with medical supplies under the charge of a surgeon of the Public Health Service.

Losses in the German Medical Corps.—According to a report from Basel, an official statement gives the German losses among army doctors during the first five months of the war as 342, of whom 112 are slightly wounded, 40 seriously, 1 ill, 65 dead (including those who died of disease), 75 missing, and 46 captured—in all, nearly 3 per cent. of the total number of doctors in the German Army.

Cost of the Antituberculosis Campaign.—In the annual statement of the National Association for the Study and Prevention of Tuberculosis, published on New Year's Day, it is shown that more than $20,500,000 was spent last year in the campaign against tuberculosis in this country. Sixty-six per cent. of the money was derived from public funds, either Federal, State, county, or municipal, and the remainder was contributed by private individuals.

Study of the Material Basis of Intellect.—At the meeting of the American Association for the Advancement of Science, held in Philadelphia last week, several speakers urged that all exceptionally brilliant men, leaders in science, art, literature, politics, and mercantile pursuits, should will their brains to science. There is already in existence an association the members of which have agreed to do this, and doubtless there are many more who think that science would gain were they themselves to join this select company.

No Speeding for Doctors.—The mayor of St. Louis has vetoed a bill passed by the municipal assembly granting physicians the right of way in the city streets. He fears advantage will be taken of this permission to indulge in needless speeding, and suggests as a substitute that physicians' motor cars carry a distinguishing mark so that the police may let them pass through processions and ride at a moderately rapid pace while on the way to urgent cases.

A State Child Hygiene Bureau.—The Governor of Kansas has promised the women of the State that he will ask the Legislature to provide for a bureau of child hygiene in connection with the State Board of Health. Practically all the women's clubs and many other organizations have asked the legislature to establish such a bureau.

Vesalius Evening at the Academy of Medicine.—The Vesalius quadricentennial was celebrated at the New York Academy of Medicine on Thursday

of this week. The following was the program of the exercises: "Vesalius and the Spirit of His Time," by Professor William H. Welch of Johns Hopkins University; "Anatomical Illustration Before and After Vesalius,' by Dr. Fielding H. Garrison, editor of the *Index Medicus;* Portraits of Vesalius (lantern slides), by Professor Harvey Cushing of Harvard Medical School. There was also an exhibition of early editions of the works and plates of Vesalius and of the anatomists and surgeons of his time, open to the public, January 5 to 9, inclusive.

Harvey Society Lectures.—The sixth lecture of the present Harvey Society course will be delivered by Dr. Edward R. Baldwin of the Adirondack Cottage Sanitarium in the hall of the New York Academy of Medicine on January 16 at 8.30 P.M. The subject of the lecture will be "Immunity in Tuberculosis, with Special Reference to Racial and Clinical Manifestations."

Examination for Physician in the Indian Service.—The United States Civil Service Commission announces an open competitive examination for physician, for men only, on February 3, 1915. From the register of eligibles resulting from this examination certification will be made to fill a vacancy in this position in the Indian Service at the Hayward School, Wisconsin, at $1,100 a year, and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion. For the position at the Hayward School, Wisconsin, unmarried eligibles without dependents are desired. Applicants must be graduates of or senior students in recognized medical schools, and citizens of the United States. The names of senior students will not, however, be entered on the eligible register, in the event they pass the examination, until they have furnished proof of actual graduation. Applicants must have reached their twenty-first but not their fortieth birthday on the date of the examination. Persons who desire this examination should apply to the United States Civil Service Commission, Washington, D. C.

Charitable Bequests.—In the distribution of the estate of the late Townsend S. Lamborn, of Bradford Township, Pa., the sum of $71,376.85 was recently awarded to the Chester County Hospital.

Under the will of the late Mrs. Emilie Huber of Brooklyn the German Hospital and St. Catherine's Hospital receive $25,000 each.

Personal.—Dr. Charles W. Burr has been appointed by the Director of Public Health and Charities Consulting Neurologist to the Philadelphia Municipal Hospital for Contagious Diseases.

At a meeting, on Dec. 22, of the Medical Board of the Bronx Hospital and Dispensary, Dr. William J. Robinson was reelected president and Dr. Martin Rehling, secretary.

Qualified Anesthetists.—The following resolution was recently passed by the New York Society of Anesthetists: *Resolved*, that it is the sense of the New York Society of Anesthetists that the administration of a general anesthetic by anyone other than a regularly qualified practitioner of medicine be not allowed; and that the County and State Societies be asked to press legislation to this end and, further, that this action by the New York Society of Anesthetists be published in all the medical journals of the State.

Public Health Lectures.—The first of the course of public lectures under the direction of the Public Health Education Committee of the Medical Society of the County of New York was given at the Academy of Medicine on Tuesday evening of this week. The lectures will be given on alternate Tuesday evenings and Thursday afternoons from January 5 to February 25. On each of these days a special subject will be discussed by two or three lecturers. The subjects are: "Influence of Street Conditions on Public Health," "Rheumatism," "Certain Methods for the Prevention of Contagious Diseases," "Some Avenues of Entrance for Our Germ Enemies," "Conservation of Useful Lives," "Common Parental Blunders in Child Training," "Facts About Foods and Drugs in General Use," "Woman's Health in Relation to Mental and Physical Efficiency." The chairman of the committee is Dr. Esther L. Jefferis; the secretary, Dr. Wilhelmina A. Ragland.

Medical Society Elections.—THE SOUTHERN SURGICAL ASSOCIATION, at twenty-seventh annual meeting, held in Asheville, N. C., December 15-17, elected the following officers: *President*, Dr. Bacon Saunders of Ft. Worth; *First Vice-President*, Dr. Thomas S. Cullen of Baltimore; *Second Vice-President*, Dr. S. M. D. Clark of New Orleans; *Secretary*, Dr. W. D. Haggard of Nashville; *Treasurer*, Dr. Legrand Guerry of Columbia. Cincinnati was selected as the next place of meeting and Dr. C. A. L. Reed was named chairman of the committee of arrangements. Drs. Joseph Tabor Johnson of Washington, and N. Shilling of Cedar Bayou, Tex., were elected honorary fellows.

THE NUECES COUNTY (TEX.) MEDICAL SOCIETY, at a regular meeting held at Corpus Christi on December 19, elected the following officers: *President*, Dr. S. T. Dodge; *Vice-President*, Dr. L. Kaffie; *Secretary-Treasurer*, Dr. A. W. Davisson.

THE NORTH TEXAS MEDICAL ASSOCIATION held its seventieth semi-annual meeting in Dallas on December 8 and 9, electing the following officers: *President*, Dr. R. W. Baird of Dallas; *Vice-President*, Dr. M. M. Morrison of Denison; *Secretary*, Dr. H. Leslie Moore of Dallas; *Treasurer*, Dr. C. R. Johnson of Gainesville; *Councillors*, Drs. C. R. Johnson of Dallas and L. H. Reeves of Decatur.

THE TRAVIS COUNTY (TEX.) MEDICAL SOCIETY, meeting at Austin on December 11, elected the following officers: *President*, Dr. J. R. Nichols of Austin; *Vice-President*, Dr. G. C. Smart of Manor; *Secretary-Treasurer*, Dr. J. C. A. Eckhardt of Austin; *Censor*, Dr. S. E. Hudson; *Delegate to the State Society*, Dr. Joseph Gilbert.

Obituary Notes.—Dr. JAMES S. SHAW, examining physician for the Actors' Fund of America and a brother of Dr. Anna Howard Shaw, president of the National Woman Suffrage Association, died in Boston on New Year's Day. He was born in Newcastle, England, in 1838, and was graduated from the Boston University School of Medicine in 1876.

Dr. ELLA AVERILL PATTERSON, formerly of Philadelphia, died at Butler, Pa., on December 17 at the age of 36 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1901. She had been a resident physician in the Philadelphia General Hospital.

Dr. JOHN D. DICKERSON of Stockton, Md., died at Wilmington, Del., December 25 as a result of heart disease at the age of 47 years. He was graduated from the Baltimore Medical College in the class of 1892. He was a member of the Worcester County Medical Society and of the Maryland State Medical

Society, and a Fellow of the American Medical Association.

Dr. JAMES S. EVES died at New London, Pa., on December 20 at the age of 67 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1872 and he was a member of the Chester County Medical Society and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. ROBERT WALTER RAMSEY died at Chambersburg, Pa., on December 26 at the age of 64 years. He was graduated from Jefferson Medical College in the class of 1874. He was for ten years a member of the Pennsylvania State Board of Medical Examiners. He was a member of the Franklin County Medical Society and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. PATRICK W. MURPHY of Canton, Mass., died as the result of an automobile accident on December 18, at the age of 38 years. He was a graduate of Harvard Medical School in 1902.

Dr. GEORGE G. HITCHCOCK of South Hadley Falls, Mass., died on December 20 after a short illness. He was born in Unionville, Conn., in 1849 and was graduated in medicine in 1870. He had practised in South Hadley Falls since 1872.

Dr. JAMES E. TALBOTT of Linton, Ind., died on December 17 after a long illness, at the age of 66 years. He was born in Putnam County, Ind., and was graduated from the Cincinnati Medical College in 1875. He practised for a number of years in Marco and removed to Linton in 1894.

Dr. ROBERT B. TRAVIS of Camden, Tenn., died on December 19, aged 84 years. He had practised in Camden for nearly half a century until his retirement some years ago. He was one of the pioneers in the prohibition movement in Tennessee.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE HOSPITAL FUNDS—DEBATE ON TETANUS, PROPHYLAXIS AND TREATMENT.

LONDON, December 19, 1914.

THE governors and council of King Edward's hospital fund met on Wednesday and awarded grants to the hospitals and sanatoria for the present year. The speaker presided and read a message from the King expressing satisfaction that in this abnormal year £140,000 could be distributed and that the services of the staffs of hospitals have been of so great value to the sick and wounded at the seat of war as well as to those who have been brought home. The awards vary with varying circumstances in each institution, but it is stated that a diminution or even an omission of an award is not an expression of dissatisfaction. Two amalgamations have been successfully arranged. It is advised that building schemes be postponed during the war and every care taken to strengthen control over the cost of working. The cooperation of the Sunday and Saturday funds is fully appreciated, and the new edition of the Revised Uniform System of Hospital Accounts is cordially welcomed.

Tetanus, Its Prophylaxis and Treatment was the subject of the session's second fixed discussion at the Medical Society of London last week. The rarity of the disease, its fatality and the fact that a number of cases have occurred among the wounded in the present war sufficed to attract a full meeting, the more so as it was said that several of the few men with special experience of the disease were expected to take part in the discussion.

Capt. D. Embleton, who has observed a series of cases at Netley and the Third London General Hospital, opened the discussion by impressing the necessity of keeping in mind (1) the spore, (2) that the bacillus is a strict anaerobe. As to the spore, it was very hard to kill, would withstand a dull red heat, while carbolic acid, 1 in 20, took 15 hours to kill it. Inoculation with a clean spore (*i. e.* one washed free from its toxin) would not produce the disease, as it was rapidly dealt with, but would do so if lactic acid or another organism was introduced with it, as trauma with lowered vitality of the tissues was thereby caused. In artificial culture the organism would only develop in the absence of oxygen, but in the body it was questionable if oxygen must be absolutely excluded. A clean spore would set up the disease when the tissues were damaged, and this is more important than absence of oxygen. It was practically certain that the bacilli migrated rapidly by the lymphatic to the thoracic duct and so into the blood. No doubt most of them were destroyed, but others might liberate toxin at a distance. It had been said swabbing the wound with pure carbolic acid would destroy the toxin. But 1 in 20 was just as efficient a germicide as pure acid, but it took 15 hours to kill spores; pure phenol, however, damaged the tissues and so prevented the blood reaching the organism and dealing with it as it can if it can gain access to it. This suggested that in cleansing the wound nothing to injure the tissues should be used but free access of blood encouraged (fomentations, hot baths, etc.). It has been proved that antitetanic serum is prophylactic, and on animals it has been shown valuable in the established disease, *i.e.*, given very soon after the first symptoms. The intravenous route might be best but might be dangerous or fatal in a person hypersensitive to horse serum or who had been previously inoculated with some antiserum (horse prepared). The *subcutaneous route* was safe, rapid enough, and could be used for large quantities. The object was (1) to destroy the circulating toxins, (2) promote phagocytosis of the bacilli, (3) destroy the toxin causing symptoms to the central nervous system. On the first symptoms 10,000 units should be injected, then 3,000 every 2 hours. But not beyond the third day, by which time the horse serum would act. Hypnotics are best withheld until severity of spasms or exhaustion of patient compel their use. When given, the dose should be such as to produce marked effect.

Professor Andrewes asserted that the bacillus did not inhabit the soil as such, but the manure of horses and cattle with which cultivated soil is contaminated. The risk of tetanus therefore depended on the presence of such contamination in any deep wound and might be estimated on either clinical or bacteriological grounds. The test on which he was disposed to rely chiefly was the presence of anaerobic bacilli in the discharge. As a prophylactic a good indication was the presence of large gram-positive bacilli resembling *B. aerogenes capsulatus* —500 U. S. A. units being an adequate dose, since that sufficed to protect a horse. In a very severe or foul wound or when considerable time had passed since infliction perhaps 1,000 units would be safer. He thought it right to give serum for a suspicious case even after 2 or 3 weeks. In the declared disease he rather favored amputation or free excision when

possible. He considered the intrathecal route the best. Statistics showed a large dose of antitoxin should be given and repeated as required. Moreover, large quantities should be given subcutaneously to keep up the high concentration in the central nervous system. After all, antitoxin could only turn the scale in a doubtful case. As to anodynes, it should not be forgotten that death was often through the respiratory system.

Dr. John Eyre agreed with Professor Andrewes as to finding gram-positive organisms, though they could not be found in several of his cases. Inoculation of a mouse caused tetanus in 2 or 3 days; so a decision as to treatment must be made on the surgical condition. Severe lacerated, contused or deep wounds were those for prophylaxis. The site of production of the toxin should get attention at the earliest possible moment. The spore did not produce the toxin, the bacillus did and was susceptible to carbolic acid. As to serum, 500 units might do if given immediately, but the danger increased so rapidly that a day's delay meant a need of 20 to 30 times as much. The serum conferred immunity for about a week, when a second dose was required. Intracerebral injection could only be justified as a last resort, though it has sometimes seemed to turn the scale. Intrathecal was the best route, his cases so treated mostly recovered, but those subcutaneously were mostly fatal. The cerebrospinal fluid ran away freely, so a considerable dose of serum could be given. Intravenous injection acted quickly, subcutaneous slowly but persistently. He recommended the simultaneous use of all three routes.

Lieutenant-Colonel Blair, R. A. M. C., had treated 17 cases in the Herbert Hospital, of which 9 recovered, 2 were still under treatment, and 6 had died. The wounds were all severe and all very dirty—generally gun-shot, not shrapnel. In 4 serum had been given before coming to the hospital—perhaps in too small doses, or not early enough. Unless seen within 2 days 4000 units should be given intravenously. At the hospital he used intrathecal injections of 4000 units daily in established cases. The cerebrospinal fluid is under pressure, so is let to run until it drops slowly and then the serum is injected—a volume rather less than that removed. Morphine, chloral, and bromide had been used. Chloretone (40 grains in 2 oz. of olive oil 2 or 3 times a day, per rectum) relieved spasms for hours when retained, but often it was rejected. Stimulants if exhaustion set in. The total quantity of serum given varied greatly, 62,000 units was the most he had used.

Dr. C. H. Browning said clearly the amount of serum needed increased enormously with the lapse of time, so the symptoms should be watched for. The danger of anaphylaxis might probably be met by injecting previously a dilute solution of antitoxin, so as to set up an anti-anaphylaxis. The blood pressure would serve to indicate the quantity of serum to be injected intrathecally—a fall of 40 mm. Hg. showed the limit of dosage was reached.

Cholesterinemia and Globular Resistance in Anemia.—G. Antonelli reports that in anemia there is no relationship between the degree of this condition and the amount of cholesterin in the blood serum or in the red corpuscles. There is likewise no relationship between the globular resistance, *i.e.* the resistance of the erythrocytes to hemolytic agents, and the amount of cholesterin either in the serum or in the red blood cells.—*Il Policlinico.*

Progress of Medical Science.

1. Forlanini's Artificial Pneumothorax. (A Study.) Parts III and IV. G. M. Balboni.
2. The Heart Action of Pituitrin Upon Acute Heart Failure and Incompensate Heart Lesions. E. Zueblin.
3. Mastitis in Pregnancy, with Report of a Case. B. R. Whitcher.

1. Artificial Pneumothorax.—G. M. Balboni discusses the avoidable accidents and complications and the results of pneumothorax treatment. The accidents are: (1) Hemorrhage due to puncture of the lung. (2) Subcutaneous emphysema the predominating causes of which are a large wound, the injection of nitrogen at a high pressure, the lack of tensity of the tissues, the excessive thinness of the subject, and a paroxysm of coughing following an injection. Pneumothorax from puncture and rupture of the lung is a serious accident. Deep or mediastinal emphysema is produced when the nitrogen is injected in large amounts into the lung. The pleural reflex described by French and Italian writers and consisting of eclamptic attacks, loss of consciousness, and sudden death, may in all probability be avoided if a preliminary injection of morphine is given. The author believes that the cases of so-called pleural shock are in reality instances of air embolism or of spreading thrombosis from the pulmonary veins. Two possible complications of artificial pneumothorax are shock from increased toxemia and acute dilatation of the heart. Gas embolism ought to be absolutely avoided. No gas should ever be introduced unless the characteristic respiratory pleural oscillations are obtained. Infection of the pleura from without may occur from the instruments used, the local anesthetic, the nitrogen or air used, the breaking of the needle, the skin, and the hands of the operator. Serous pleural effusion may develop any time after the induction of the pneumothorax when the lung is wholly or only partially collapsed. These effusions are unfavorable complications inasmuch as the presence of a large number of tubercle bacilli in the pleural cavity increases the absorption of toxins; nevertheless they must be interfered with as little as possible unless they become too large or show continued unfavorable symptoms, such as continued pyrexia, marked distress and disturbance to the adjacent organs, or its character changes from serous to purulent. The danger of infection becomes greater at secondary injections, as the fluid is an excellent culture medium. A serous effusion may be transformed into a purulent one. Pain may result from separation of the pleural surfaces and the stretching of adhesions. In the beginning most of the patients lose weight.

2. Pituitary Extract and Heart Failure.—E. Zueblin reports a series of cases representing a clinical study of this subject. He finds that a too extensive dose of pituitary extract in advanced age may result in a sudden harmful rise of pressure. The sudden change may be undesirable for the vessels of the brain and may be complicated with hemorrhage and apoplexy. In a weakened and tired-out myocardium the distended organ may be rapidly reduced to a more normal size. In cases with but little reserve strength left, there remains a possibility that pituitary extract may help the immediate needs and that after the diminution of dilatation has become noticeable, the patient, before intolerant to the ordinary cardiac stimulation, may again be able to stand a careful test with these routine remedies. In doubtful cases, in which there may be sclerotic changes, especially sclerosis of the coronary vessels and stenocardia, pituitary extract may hasten a fatal result.

3. Mastitis in Pregnancy.—B. R. Whitcher concludes that organisms are present on the nipples in 100 per cent. and in the milk ducts in 86 per cent. of all pregnant women. When the tissues have been injured by trauma and their resistance lowered, or the breasts have become more engorged, or the organisms are of unusual virulence, they attack the tissues and produce inflammation. The prophylaxis of breast abscess in pregnancy consists in absolute cleanliness of the nipples, and avoidance of injury to the breasts; and prompt treatment of mastitis by bandaging, ice packs, cold astringent compresses, and saline catharsis is also necessary by way of prevention.

8. Wounds of Arteries. S. Erdman.
9. Industrial Sanitary Standards. G. M. Price.
10. Tuberculosis of the Tongue. J. Weinstein.

1. Astasia-Abasia in Multiple Neuritis.—C. W. Burr reports a case presenting this association in a male, aged 45 years, in whom an hysterical element was prominent. It was difficult to decide whether there was anything more than an accidental relationship between the neuritis and the ataxia. The neuritis itself, if a cause, could act only by autosuggestion. The author believes that in this case the hysteria as well as the neuritis was alcoholic with a wretched heredity as a predisposing cause.

2. Physical Defects and Crime.—By E. W. Lee. (See MEDICAL RECORD, Vol. 86, page 1080.)

8. Wounds of Arteries.—S. Erdman states that the partial division or "nicking" of a medium sized artery is more liable to give rise to secondary hemorrhage than is its complete divison. Successful temporary hemostasis may be attained by ligatures applied at random in the depths of the wound and by closure of the wound; but if the lumen of the artery is not obliterated. even after three weeks of absolute hemostasis, severe secondary hemorrhage may occur. In the two cases reported by the author, the pulse could be felt distal to the site of injury, and during the secondary hemorrhages there was no spurting character to the flow, owing to the very indirect channel from the artery to the skin; hence the arterial origin of the bleeding was not suspected by the physicians first in attendance. Hemostasis in all cases of profuse bleeding from wounds in the vicinity of arteries should be accomplished by ligatures accurately placed under direct inspection by the operator, and whenever necessary the wound must be sufficiently enlarged.

10. Tuberculosis of the Tongue.—J. Weinstein reports a case of this condition in a male patient aged fifty-five years in whom it was difficult to determine whether the infection was primary or secondary. The difficulty of diagnosis in this condition has been referred to by W. B. Trimble, who has noted the impossibility in most cases of demonstrating the bacilli in the ulcer. He has also concluded that although lues and cancer furnish the majority of ulcerations of the tongue and mouth, they are by no means the only causes. In any case of tongue ulceration, tuberculosis must be reckoned with as a factor. The histopathological examination alone is practically useless as a means of diagnosis between syphilis and tuberculosis, but it is a great aid in excluding cancer.

16. Oidiomycosis in Porto Rico. E. R. Hildreth and A. C. Sutton.

3. Subtotal Cystectomy.—J. Bentley Squier states that the operative treatment of tumors of the bladder has been inadequate in preventing local recurrence and implantation metastases. In a case of malignant tumor, the tumor *per se* should not be handled and the excision must be through all the coats of the bladder and the peritoneum adjacent to the bladder wall if found to be infiltrated. The wide denudation can be made with the patient in a high Trendelenburg position, either intraperitoneally or extraperitoneally. The vas deferens in the male offers the most reliable and quickest way of reaching the terminal ureter. The blunt dissection along the lateral walls of the pelvis allows for the exploration about the ileac vessel for metastatic glands. In the female the relation to the uterine artery allows for an accurate localization of the terminal ureter. Any cystectomy for vesical tumor should be radical. In substance there is no difference between intraperitoneal and extraperitoneal surgery for this class of work. Leakage, if it does occur, does not take place into the peritoneal cavity when the peritoneum has been sutured carefully with a serous approximation of surfaces. If after opening the bladder a malignant neoplasm is excavated or sessile, cauterization of the base or surface of the tumor is a procedure of undoubted palliative value. After excision, searing the cut edges before suturing is a very wise precaution. The use of 50 per cent. resorcin or 1:5,000 mercuric chloride swabbed about the bladder, is useful in destroying any detached tumor particles.

4. Cysts of the Metacarpal Bones.—P. G. Skillern, Jr., reports two cases presenting minute cysts of the metacarpal bones and concludes as follows: Cysts of bone should be detected in their incipient stages before extensive destruction of the medulla has taken place. Early operation results in prompt cure, and prevents deformities and extensive bone plastics. A localized trauma followed by persistent but not severe pain, and localized but not true "wincing" tenderness—symptoms and signs of an untreated "chipping" fracture—should arouse clinical suspicion of a minute, early bone cyst, the corroboration of which may be afforded by close scrutiny of a roentgenogram at the site corresponding to that of the localized tenderness.

10. Lymphocytic Picture and Albumin Content of Sputum.—J. Ritter concludes that sputum lymphocytosis showing under the microscope 50 per cent. or more of the small mononuclear leucocytes (lymphocytes) with a moderate amount of albumin by chemical

test speaks very strongly for the presence of a pulmonary tuberculosis. In preincipient or incipient cases of pulmonary tuberculosis a lymphocytic sputum is usually present with a greater or lesser albumin content; in this the tubercle bacillus may be entirely absent or only an occasional bacillus found. The presence of the mononuclear lymphocyte in sputum in preponderant amounts and a positive albumin test, is simply the forerunner or near the beginning of positive findings, for the tubercle bacillus if not already present in the expectorations will soon be found. In a sputum giving a lymphocytic picture in the absence of tubercle bacilli, a positive albumin content has been demonstrated; this is confirmatory evidence that the sputum is that from a person suffering from pulmonary tuberculosis, and hence a careful microscopic study of every sample of sputum under examination should first be made for either the presence or absence of the tubercle bacillus; if this is negative and with a preponderance of the small mononuclear leucocytes in every field with a positive albumin finding by chemical test, in moderate amount, one is justified in assuming that the source of this expectoration is that found in a positively tuberculous individual.

7. The Treatment of Wounds in War. Sir Anthony A. Bowlby.
8. Our Army's Teeth. F. Newland-Pedley.

1. Pathology of Mental Disorders.—E. Goodall finds that the observations of many workers upon the leucocyte count in the psychoses point to the conclusion that a leucocytosis with a neutrophile increase would favor the diagnosis of a toxemia, though not a grave one. There is also evidence of a lymphocytic reaction in paresis, with a neutrophilic predominance and exacerbations. The modern work in the ferments and antiferments in psychiatry suggests the hope that one may be able to distinguish between functional and organic disease. The author calls attention to the frequency with which intercurrent disease brings about an amelioration or cure of mental maladies. He next discusses the newer methods of treatment with nucleinate of sodium and leucocyte extract.

3. A Treatment for Prolapsus Ani in Young Children.—W. Gemmill points out that while the accessory forces consisting in the flexion of the thighs on the abdomen and the contraction of the abdominal muscles are of great advantage in defecation in normal health, they are of decided disadvantage in the treatment of prolapse, and especially is this the case when the prolapse is complete, in which type the accessory forces are doubtless the chief expelling factors. The principle then in treatment is to remove these forces as far as possible, and to bring about a condition in which the abdominal capacity responds passively to the decrease in contents brought about by the evacuating contractions of the large bowel, and is not actively decreased by the strength of the accessory forces. This is attained simply by preventing the flexion of the thighs and spine. A straight wooden splint, well padded and covered with rubber tissue, is applied to the back of the child of a length to reach from the neck to the heels, and the child is fixed to the splint by two bandages, one round the thorax and the other round the lower limbs. More recently the author has been using a similar splint with a hiatus in the region of the anus bridged by a circle of iron, as shown in the diagram. This allows defecation without soiling the splint, and also easy access for such local treatment as cold douching, etc. The result obtained is that the extended position of the child prevents the action of the accessory forces in great part, for the abdominal muscles are placed at a disadvantage for contracting. This position also prevents the decrease in abdominal capacity from flexion. Hence evacuation takes place almost entirely from the muscular action of the great bowel. The removal also of the natural support which the soft parts give to the anal canal and sphincters is prevented, and the splint itself gives additional local support by pressing on the soft parts of the buttocks, from which it follows that the hiatus must not be too large, a condition in which this local pressure would be lost. The relief which this method gives is immediate, the bowel remaining in the abdomen after reduction from the beginning and no prolapse occurring even during defecation, for which the splint must not be removed. The advantages are efficiency, simplicity, and a minimum amount of trouble in the management of the child, who soon becomes quite comfortable and happy. The splint may be retained as long as is necessary for the child to regain health, for the sphincters to retain tone, and for a normal condition of the parts to return.

4. Delayed Chloroform Poisoning.—H. P. Fairlie reports a case of this condition in which the definite symptoms did not develop for considerably more than 48 hours after the administration. Buxton gives the usual time of onset as from 12 to 42 hours, and Hewitt from 10 to 48 hours after anesthesia. After the onset of symptoms the case ran a very rapid course, persistent vomiting commencing only 16 hours before the end. Owing to the employment of the Vernon-Harcourt inhaler the amount of chloroform administered was small relative to the length of anesthesia, the importance of which Buxton emphasizes.

1. The Work of the "Clearing Hospitals" During the Past Six Weeks. Sir Anthony Bowlby.
2. Permanganates in Sloughing and Tetanus-Infected Wounds. Sir Leonard Rogers.
3. Iodine as an Antiseptic in Joint Injuries. A. Gascoigne Wildey.
4. A Simple Form of Portable Dressing Sterilizer. C. W. Cathcart.

1. Work of the "Clearing Hospitals."—Sir Anthony Bowlby records his experiences as consulting surgeon to the British expeditionary forces in the Ypres district. The magnitude of the work confronting the surgeons at the clearing hospitals may be realized when it is stated that on many days from 500 to 1,000 or more wounded have arrived at a single clearing hospital in twenty-four hours. Many of the wounded arrive in a dying condition, especially if there is a wound of the brain. Chest wounds are tolerably common. The abdomen is to a great extent protected in the trenches, and abdominal wounds are not as relatively common as they were in South Africa. Injuries of blood vessels have in many cases caused gangrene without causing serious bleeding. Tetanus is not as common as on the Aisne owing to the different nature of the ground and the preventing inoculation. While true "hospital gangrene" has not been observed in any hospital in France, "spreading gas gangrene" has attacked 0.5 per cent. of all the recent wounds of all the armies. True pyemia has not been seen or heard of by the author.

2. Permanganates in Sloughing and Tetanus-Infected Wounds.—Sir Leonard Rogers believes that the use of strong permanganate solutions, not less than 1 in 500,

for irrigating all dust- and earth-infected wounds is worthy of trial in the field. The crystals are so easily carried and the solutions so harmless that this simple plan could be easily carried out at the dressing stations in the case of all wounds in which any sloughing or suppuration has already commenced, or into which dust or earth is likely to have penetrated, with good hope of lessening the number of cases of tetanus, septic and anaerobic bacillary infections.

Wounds Caused by Indirect Projectiles; Dangers of the Wrist Watch.—By "indirect projectile" Melchior means anything not directly aimed or anything not intended as a projectile. In plainer language any object of stone, woodwork and the like detached by actual projectiles or exploded in any fashion which can and often does inflict a wound. In sea warfare this is seen especially in splintering of the woodwork on battleships. The author, however, deals in this paper with hand fighting. As the velocity of these secondary projectiles is not necessarily high, there is chance for some protection in the direction of padded wearing apparel, etc. But the helmets, buttons, solid objects carried in the pockets, while they at times serve as protection, often themselves contribute to injuries and habiliments of this class ought when possible, to be eliminated. In this connection we learn that many German officers and soldiers carry the wrist watch worn on the left side; and the fact that exposed parts like the face and hands are more often injured than the unexposed surfaces would appear to make the custom of wearing a wrist watch at the front of doubtful advisability. In the present as well as the Balkan wars, the frequency of injuries to the left hand from infantry bullets has often been the subject of comment. Thus a German officer in the Poland campaign was struck by a shrapnell bullet directly upon his wrist watch, the latter being smashed to atoms. After first dressings the patient was sent to Breslau, where he arrived three days later, his dressings saturated with foul pus. The forearm was found to be gangrenous. The *x*-ray showed a comminution of the wrist bones and radius and the presence of embedded metal splinters from the watch. The hand may be saved but the functional result will be bad. This type of accident is not unique for the author knows of another case. The wearing of wrist watches invites these severe injuries and the author warns against the custom.

Treatment of Neuralgia and Neuritis with Bacterial Toxins.—Dölken begins a dissertation on this subject. The neuralgias and neuretes have never been known to be favorably acted on by suppuration anywhere in the body. Nevertheless by the use of bacteriotoxins rapid cures of these maladies have been effected. The author commenced this study in connection with the pains of tabes dorsalis. The patient who had developed incidental furunculosis was under treatment for the latter with staphylococcus and streptococcus vaccines. No benefit being observed, various other vaccines were tested. The most efficacious among these was the Shiga-Kruse dystentery culture and the next best the hyoscyamus. Both vaccines, however, caused a remarkably strong local reaction. Bacterial extracts showed no advantages nor did autolytic vaccines. The author then turned his attention to the bacteriotoxins. While staphylovaccine had appeared to be inert staphylotoxin at once caused prompt therapeutic effects, when tested in case of trifacial neuralgia. The latter is therefore neurotropic. The author now mixed autolysates of the bacillus prodigiosus and the staphylococcus with the intention of increasing the powers of the latter. A long account follows of the local and general reactions and the therapeutic effects, but as the preparation will be marketed under a proprietary name with withholding of some of the data of preparation, it will have to win us some way before general recognition is accorded it.

Limits of Organotherapy.—Münzer states that in organotherapy a dead, alien and undosed substance is incorporated into an organized being nourished by living warm blood and regulated by the most delicate nervous mechanism. If such passed through the stomach it may be rendered inert by the action of the digestive juices. At the other extreme we see thyroid substance cure a condition which *prima facie* would seem to be irremediable by any plan of treatment. How can we reconcile such opposites? Abderhalden has done much in the borderland between these extremes. The substances, dead and foreign though they be, are able to provoke the formation of native defensive antibodies. This blood foreign matter, moreover, was formed within the body, and evidently through functional insufficiency of one or more of the glands of internal secretion. Hypersecretion of a gland doubtless is best considered as a reaction against diminished secretion of other endocrinic glands. In hyperfunction which leads to some disease, the latter may sometimes be cured by feeding with the antagonists. The great importance of the thyroid is due to the fact that it possesses functions which are absent in several other glands, and can take over their work when they become insufficient.

November 24, 1914.

Successful Treatment of Tic Convulsif with Calcium Chloride.—Emmerich and Loew report cases of this sequence. One patient was 49 years old and 20 years before had been attached by cloni in the trapesius, splenicus and other neck muscles on the right side, also the flexors of the right forearm and of the fingers of the right hand. His head was drawn to the right side a number of times a minute. Many years later when seen by one of the authors the patient was a physical wreck. The number of tics per minute had increased visibly until they now numbered 45. There was some muscular hypertrophy on the affected side with slight atrophy on the opposite side. The tics had become more violent and at times the head was literally snapped to the right. It was found that patient had always been a great meat eater. Vegetables and fruits he seldom touched, nor did he drink milk. The amounts of lime and magnesium consumed were found to be very low, despite the fact that he took plenty of nutriment. As is known, lime deficiency is responsible at times for weakness of the muscles and clonic convulsions. The amount of magnesia taken was large enough to disturb the lime metabolism. Patient was placed on vegetables rich in lime and a 20 per cent. solution of chemically pure calcium chloride. The tic frequency gradually came down to 7 per minute and finally ceased while muscular strength and energy returned. Another favorable result was also secured in the same manner. Oppenheim has stated that these tics of the neck and shoulder are among the most refractory of all diseases. One of the authors (Loew) had made the discovery that the affection is due to calcium deficiency in the cell nuclei. However, the mineral must be given for months at a time to obtain positive results. The authors believe it worth a trial to administer this treatment to myoclonic subjects.

Complement Fixation in Variola.—Klein concludes after his research on this subject as follows: It is certain that in the serum of variolous subjects antibodies are demonstrable by the aid of the complement fixation reaction. This reaction in variola differs from the seroreaction in syphilis. In contrast to the latter it is specific, *i. e.* there is a genuine antigen-antibody reaction. In all probability the exciter of variola itself represents the antigen. As antigen, material from variola pustules alone seems to suffice. All other antigens are untrustworthy and should therefore be rejected. The greatest constancy is seen when variola scabs are employed.

Surgical Experiences at the Front.—Danielsen, attached to the army of the Crown Prince has treated 4500 wounded at the front. The Sanitäts-kompagne to which he is attached treats all wounded infantry during and after the fighting—in other words give first aid dressings. The wounded are brought by orderlies on stretchers to the nearest dressing station, where nine surgeons are detailed to attend them. All life-saving operations which are indicated are at once performed (hemostasis, tracheotomy, etc.). The site of a dressing station is determined in advance by a division surgeon and is often difficult to find. It should be on a main road and in a solidly constructed structure, either a building or something extemporized. There should be easy access, for a narrow portal, as in a private house, causes constant blocking. The rooms must all give upon corridors. Nothing answers the purpose as well as a barn with its wide entrance and space for supplies of all kinds. Several barns which lie close together make a good dressing station. Churches and school houses also do very well. "Space and transportability" are the two watchwords. The signals are a red cross flag on a pole and at night a red lantern. The author always operated with clean rubber gloves. Wound areas were disinfected with iodine tincture (personally the author has no faith in the efficacy of this procedure). Very disagreeable is the lack of pledget material. A general prognosis of gunshot wounds is impracticable. The author has been very conservative about amputations. In the first 4000 wounded he did two amputations, at the arm and forearm respectively. There were 83 skull wounds, in which as a rule the brain was involved. The 89 thoracic wounds were benign as a whole. Of 63 abdominal injuries the vast majority proved fatal. A few patients who survived were sent to the field hospitals. The author's experience directly opposes the view that these cases pull through in large numbers under conservative management. The number of fractures was very great —109 of the thigh alone, 71 of the upper arm, etc.

Deutsche medizinische Wochenschrift.

November 26, 1914.

Gas Phlegmons.—Tietsche and Korbsch refer to the warm, dry weather at the outbreak of the war, which in part favored the clean healing of the wounds. Later the weather became wet and shell wounds increased in frequency as a result of day-long cannonading, which at the same time prevented prompt dressing of wounds. Along with ordinary infection and tetanus, gas phlegmons began to appear. In all cases a bacteriological examination was made and in several a new gas bacillus was isolated in pure culture. It then became practicable to trace the disease type from its inception to its occasionally fatal ending. Thus a soldier was struck on the right buttock by a fragment of shell. The wound was round, the size of a penny, with shredded edges and secreted a thin fluid. It was seated at the upper and central portion of the buttock which was markedly swollen and sensitive to pressure. There was no fever and the local wound reaction was not marked; so that a mere occlusive dressing was applied (24 hours after the injury). The same night a temperature of 40° C. developed and the buttock having steadily increased in size the wound tract was incised. The contents of the latter, which consisted of coagula, having been removed, the muscles were seen to be swollen succulent, friable, their blood vessels thrombosed. There was, however, no odor of gangrene or discolored pus. The bacillus in question was found in smears. Simple incision and drainage caused conditions to rapidly become normal. In another patient with a similar wound on the anterior surface of the thigh, the exposed muscle tissue seemed quite normal, with no pus in the course of formation. Blackish areas at the wound margin appeared to be due to dirt. There was no local reaction, so that a simple dressing was applied. The characteristic bacillus was found in smears. Within two days the wound began to swell, but without crepitus or gangrenous discoloration. The discharge, however, became dark, contained gas bubbles, and gave off an intense gangrenous odor. The wound cavity was at once exposed and hydrogen peroxide applied, prompt improvement following. Both these cases were aborted yet without resort to any special form of wound treatment. In cases unfavorable for drainage the condition naturally progresses. The authors cite the case of a wound of the face from a small shell fragment, in which the nasal and orbital cavities were both involved. There was a broad opening of exit over the opposite temple. The left orbit was exenterated and the wound tract laid open and treated with peroxide. Further history of the case is not given. While superficially the wound tract seemed in a fair condition the pit of the wound funnel was gangrenous. A very different type of wound is that which becomes gangrenous at its inmost portion, the process extending rapidly to the surface. It is this type in which pent up gas collects and percussion will sometimes bring out a hollow note like that from percussing a cardboard box, even while the surface is not much affected. Naturally an entire limb may be quickly affected and upon removing dressings applied three days before for shell wounds of the arm, the entire limb may be found ripe for amputation. The authors have thus far seen 12 cases of gas phlegmon in a material of 300 wounded. Two deaths occurred. The lower extremities constitute by far the most frequent site of gas phlegmon.

Removal of a Large Pharyngeal Pouch under Local Anesthesia.—W. H. Kelson reports the case of a man aged 70 who was admitted into the London Throat Hospital in November, 1913, with the diagnosis of stricture of the esophagus. He was stated to have had increasing difficulty in swallowing for four years, and to be getting steadily thinner and weaker. After careful examination the author's suspicions were aroused as to the correctness of the above-mentioned diagnosis, and at his request an *x*-ray examination was made, and clearly demonstrated the presence of a pouch dipping down to the aortic arch and lying behind and a little to the left of the esophagus. As the patient appeared to be going down hill somewhat rapidly it was decided to operate, and to avoid all risk of postanesthetic vomiting the author decided to use local anesthesia. Operation was performed December 3, after the injection of a solution of cocaine and morphine along the line of the proposed incision. Hemorrhage was trifling. It was found necessary to divide the omohyoid muscle.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

Overweights.—One of the most important factors in medical selection for life insurance is the applicant's build. Dr. H. A. Baker, Medical Director Pittsburgh Life and Trust Company, states that it was formerly supposed that the average build represented the best mortality at all ages and medical selection has been based upon this theory, but the recent work of the Medico-Actuarial Investigation has shown that the best mortality is not found among those of average build at all ages, but in those at the younger ages who are slightly overweight, and at the older ages among those who are distinctly underweight. This committee compiled a table called the M. A. table—a standard table of mortality which could be used for testing the degree to which the mortality of the various classes differs from the average combined experience of all the companies. Overweight has long been regarded as a serious impairment to a life insurance risk. In judging overweights found in insurance work, one can be reasonably certain that in the majority of cases it was stated that "No excess adipose tissue was present," also that "The overweight was due to muscular development." Such, however, is not the case and the law of general average cannot be escaped. According to the arrangement of the M. A. table slight corrections must be made in the case of very short or very tall men, as the given departure from the standard is a greater percentage in the case of a short man than of a tall man. Therefore in the overweights we should make the percentage mortality slightly higher for very short men and slightly lower for very tall men. Men from twenty to twenty-four years of age can be accepted fifty to sixty pounds over the normal showing a mortality of only 110. Ages twenty-five to twenty-nine with the same overweight show a mortality of 116, and sixty-five to eighty, overweight the same, show a mortality of 132. At the ages thirty to thirty-four we begin to reach a high mortality at thirty-five to forty-five pounds over the standard. In the next group, ages thirty-five to thirty-nine, the mortality becomes excessive when thirty-five pounds over the standard is reached, and for all ages over forty this table shows that applicants who are more than thirty pounds overweight must be considered sub-standard risks. At age forty, height five feet, eight inches, thirty pounds over the standard represents 19 per cent. overweight. There are some factors which make an overweight a much more desirable risk than the average overweight, while there are other factors which make him a much poorer risk. Among these factors are occupation, habits, family history, personal history, abdominal measurement, blood pressure and the personal equation. Occupation.—Dr. Baker considers that in the most favorable occupations, such as lawyer, clergyman, teacher, etc., a deduction of ten to twenty points can be made from the table, while in the case of a hotel keeper, a rating for overweight should be added to the rating for occupation. Habits.—In the case of abstainers from alcohol it may be considered safe to deduct twenty points from the overweight table, and ten points in the case of those who now abstain, but who in the past have used alcohol in moderation. This will bring many overweight abstainers within the standard class. However, the slightest use of alcohol in an overweight must be viewed with grave suspicion. Alcohol and overweight go hand in hand to an early mortality. Deductions should not be cumulative. If you have deducted twenty points because an applicant is a clergyman you should not deduct twenty points more because he has always been a total abstainer. Family History.—It is safe to conclude that a maximum deduction of twenty points can be made from the M. A. table in the case of applicants whose family history shows the highest degree of longevity, and a deduction of ten points in the case of applicants where the family history is undoubtedly better than the average family history represented in this table. Personal history.—Nothing can be deducted from the table for a fine personal history. Suffice it to say that any impairments, such as gout, rheumatism, syphilis, and all other diseases which constitute an impairment, must in each case be added to the rating for the overweight, making a sub-standard risk. Abdominal measurement.—A certain percentage must be added in each case where the abdomen is larger than the chest. It will be reasonably safe to add to the M. A. table ten points for each inch that the abdominal measurement exceeds the maximum chest measurement. Blood pressure.—There are no published figures on blood pressure as applied to overweight. Dr. Baker considers it would be fair to deduct ten points from the table for an exceptionally good blood pressure associated with pliable arteries. The slightest indication of high blood pressure in an overweight is sufficient to sub-standardize the risk to a point where rejection becomes a necessity. Personal equation.—After all is done and our overweight has been rated in strict accordance with scientific principles, there still remains that intangible element of personal opinion. Let us, therefore, make our exceptions few and far between, particularly with regard to overweights, and if one ever has to be made let it be because the moral and financial elements of the case are exceptionally perfect and not because there is a "hunch" that the risk will pull through in spite of his overweight.—Medical Section, American Life Convention.

The Sphygmomanometer in Life Insurance.—J. W. Fisher states that his prediction made in 1911 that the sphygmomanometer would become indispensable in life insurance examinations has now been fulfilled. Its use demonstrates in many cases, as nothing else can, the existence in apparently normal persons of an abnormally high blood pressure which seriously affects them as life-insurance risks. The author gives the experience of the Northwestern Mutual Life Insurance Company since the year 1906. At first the blood-pressure test was required at ages only from 40 to 60 by examiners in the large cities, but since November, 1911, it has been required at all ages irrespective of amount of insurance. Tables are given showing the company's experience and the higher mortality over the general average of the company in cases with high blood-pressure. The author is firmly of the opinion that a persistent blood-pressure of 15 mm. Hg above the average for the age of the applicants should excite suspicion and call for further examination. The blood-pressure should be taken with the person in a sitting posture, with the arm resting on a table or other rest, before and after the physical examination is taken.—*Journal of the American Medical Association*, November 14, 1914.

Book Reviews.

THE FECES OF CHILDREN AND ADULTS. By P. J. CAMMIDGE. Price, $5. New York: Wm. Wood & Co., 1914.

THE author has written a very complete book on the examination of feces. He has this to say as to the amount of time for the passage of food: "The clinical importance of an accurate determination of the time spent in the alimentary tract by the food lies in the information it affords as to the particular position that is concerned in the production of a diarrhea or constipation. By means of a bismuth meal and the fluorescent screen the actual progress of a test meal can be watched and its course compared with that of the healthy individual. The radiographic method is not, however, always available an dmuch may then be learned by the administration of carmine or charcoal capsules. If in a case of diarrhea it is found that the time of passage is approximately normal, it will suggest that peristalsis in the small intestine is not increased, and that the disturbance is in the lower part of the large intestine. A too rapid appearance of the coloring matter in the stools would, on the other hand, point to the seat of the trouble being in the small intestine or ascending colon. In a patient who has a daily motion, a failure of the distinctive color to appear in the next day's motion when it has been given at breakfast, points to there being latent constipation. If the bowel is then washed out and colored feces are brought away there is retention in the lower bowel; but if the feces are uncolored, there is delay in the cecum or ascending or transverse colon. The recovery of colored feces by lavage of the bowel on the morning following the administration of a cachet in a patient who does not have a daily motion, would show that atony or dilatation of the lower bowel was an important factor in the production of the constipation. The appearance of colored feces for several days after the administration of a cachet points to atony of the bowel and latent constipation."

Cammidge in describing the gross appearance and the color of various stools describes concisely the character of bilious stools. "Bilious stools are bright golden yellow in typical cases, but may have a greenish tint, or even be dark green. The presence of unaltered or but slightly altered, bile pigment in the feces of adults is always pathological, unless it is due to calomel, and indicates the hurried passage of the intestinal contents through the bowel."

After giving detailed descriptions and numerous good illustrations of the normal and abnormal elements found on microscopical examination of the stool, the author proceeds to the chemical examination of feces, for which he gives precise and very clear directions.

Cammidge's work is very practical and contains valuable points with regard to the management and treatment of intestinal disturbances. It can be highly recommended as a useful book.

MODERN MEDICINE. Its Theory and Practice in Original Contributions by American and Foreign Authors. Edited by Sir WILLIAM OSLER, Bart., M.D., F.R.S. Regius Professor of Medicine in Oxford University, England; Honorary Professor of Medicine in the Johns Hopkins University, Baltimore; Formerly Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia, and of the Institute of Medicine in McGill University, Montreal, Canada; and THOMAS MCCRAE, M.D., Professor of Medicine in the Jefferson Medical College, Philadelphia. Volume III, Diseases of the Digestive System—Diseases of the Urinary System—Second Edition, Thoroughly Revised. Price, $6.00. Philadelphia and New York: Lea and Febeiger, 1914.

WHEN Osler's "Modern Medicine" first appeared, it was recognized not only that there was room for such a work, but that in many respects it supplied a want. It was concise, well written, and authoritative. This the second edition comprises all the merits of the first, and has been brought thoroughly up to date. The articles contributed by those who are now dead have been revised by men distinguished in the subjects of which they treat and the entire volume may be regarded as a reliable book of reference. The diseases of the digestive system are the most important of those which affect man, and especially civilized man, and it is therefore essential from the medical standpoint that they should be discussed wisely and that practical measures for treatment should be suggested. Among the most valuable contributions to the present volume are the introductory chapter on diseases of the digestive system by Charles G. Stockton of Buffalo, functional diseases of the stomach by Julius Friedenwald, organic diseases of the stomach by Charles F. Martin, diseases of the pancreas by Eugene L. Opie, diseases of the peritoneum by Humphrey Davy Rolleston. Dr. McCrae writes an excellent introduction to diseases of the kidney and also discusses malformations of the kidney and circulatory disturbances of the kidney. Anomalies of urinary excretion are dealt with by a master of the subject, A. E. Garrod, while Thomas R. Brown, in one of several articles he contributes, gives a particularly lucid description of tuberculosis of the kidney. The volume as a whole may be termed a pleasingly clear and sufficiently comprehensive consideration of the diseases of the digestive and urinary systems.

THE DOCTOR'S VIEWPOINT. By JOHN BESSNER HUBER, A.M., M.D. Editor, "The Dietetic and Hygienic Gazette"; author, "Consumption and Civilization"; member of the New York Academy of Medicine. Price, $1.00. New York: Gazette Publishing Company, 1914.

IN his preface the author states that "Much of the interest of life lies in how we appreciate one another's way of looking at it—the way of the counsellor, the sky-pilot, the painter, the farmer, the man in the street, the woman in the wrapper." The volume is a series of short essays in which the writer endeavors to color with the doctor's way of thinking almost every subject under the sun from the killing of fleas to the philosophy of prayer, touching in his course the achievements of preventive medicine, the problems of tuberculosis and cancer, eugenics and euthanasia, medical and psychical research. These essays will perhaps be more interesting to the laity than to the profession, but contain withal considerable truth presented with more humor than one would suspect the subjects capable of being treated with. The author's style is easy and his book is interesting.

A TEXT-BOOK OF THE DISEASES OF THE NOSE AND THROAT. By JONATHAN WRIGHT, M.D., Director of the Department of the Laboratories, New York Post-Graduate Medical School and Hospital, and HARMON SMITH, M.D., Surgeon to Throat Department of the Manhattan Eye, Ear, Nose and Throat Hospital; Clinical Professor of Laryngology and Rhinology, Cornell University Medical School. Octavo, 683 pages, with 313 engravings and 14 plates. Price, $5.00. Philadelphia and New York: Lea & Febiger, 1914.

THIS new text-book of laryngology is a notable addition to the subject. While essentially, by reason of its clarity of statement, logical plan, and unusual literary style, all that a text-book shoud be, it is, moreover, a most comprehensive general treatise on its subject. Both text and illustration give abundant evidence of painstaking effort in the accumulation of material and its preparation for presentation. The feature that at once distinguishes this book is the emphasis laid upon the etiology and pathology of disease. Recognizing this as essential to logical and scientific procedure, the authors advance in their discussion of nasal, laryngeal, and pharyngeal morbid processes from an etiological and pathological basis. While it has been their aim to give causes and consequences the consideration due their importance, this has not been accomplished at the expense of other aspects. The consideration of symptomatology and diagnosis and the topical and operative treatment of diseases of the upper air passages follow in natural and logical sequence and in no less comprehensive detail. Much of the work in etiology and pathology rests on original investigation in the laboratory and clinic extending over many years. While the authors' familiarity with the extensive literature of this subject is evident, reference and historical allusion are studiously subordinated to the presentment of original research and conclusion. An easy literary style carries the attention of the reader, while the illustrations are so complete, detailed, and extensive, as to be remarkably illuminative. While planning a text-book, the authors have succeeded also in recognizing and emphasizing exactly what is required by their fellow practitioners. In its nearly 700 pages is comprised practically the sum total of present-day knowledge in laryngology, so logically arranged, with such a wealth of illustration, with all procedures so clearly set forth, that it should be of the utmost value to every general practitioner who treats the nose and throat, as well as to the specialist in this field.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held November 6, 1914.

DR. C. A. MCWILLIAMS IN THE CHAIR.

Infected Hydronephrosis Due to Renal Calculi. — Dr. H. D. FURNISS presented a patient who was 39 years of age, had had five children and gave a history of infection after the birth of the first, the nature and location of which was not obtainable from the history. For three and one-half years she had suffered from pain in the left lower part of the abdomen which radiated to the back and down the leg, the pain coming on three or four times a day and lasting ten minutes. In October, 1913, the patient had had an interposition operation for prolapsus. When first seen by the speaker she complained of pain in the left lumbar region and marked pyuria. Examination of the bladder showed, after indigo-carmine injection, normal elimination from the right side and none from the left. Radiograms showed several shadows in the region of the right kidney. The left kidney was removed and on section showed a large hydronephrotic kidney with several stones in the calices and one in the pelvis. The patient made an uneventful recovery.

Calculus Pyonephrosis.—Dr. H. D. FURNISS presented this patient who was 35 years of age and gave a negative history until four months ago when she began to lose in weight, had slight pain and enlargement on the right side of the abdomen, amenorrhea, for four months, pyuria for two, chilly sensations, and night sweats. Examination showed a large mass extending from the free border of the ribs downward to an inch and a half below the spine of the ilium and extending inward almost to the mid-line. Cystoscopy showed a mild cystitis with only slight redness around the right ureteral orifice. Intravenous injection of indigo-carmine showed no elimination from the right ureter. Radiographs showed small and large shadows. The kidney was removed through an oblique incision without rupture. On section it was found that there was practically no cortex left and that the kidney consisted of communicating pockets filled with pus. In the pelvis was a large stone and in the lower calices two smaller ones. It was noteworthy that this kidney went on to complete functional destruction with very little local evidence of its presence. The patient made a smooth and uneventful recovery.

Fatty Degeneration of Kidney Due to Calculus.—Dr. FURNISS presented this patient, a woman, 67 years of age who gave but little history. She had had pain in the region of the left kidney of a dull aching character and frequent urination for seven years. She had had hematuria for a short time. Cystoscopy showed some redness around the left ureter, pus coming from it and there was no elimination of indigo-carmine from this side. Radiographs showed the presence of a shadow in the region of the left kidney. This kidney was removed and was most densely adherent. Upon section it was found that the kidney had been converted into a hard, tough fatty mass, and that there was only a small portion of kidney substance remaining at the lower pole. The patient made a good recovery, though there was still a small amount of pus coming from the left ureter, for which treatment would have to be directed to the ureter itself.

Atrophy from Ureteral Calculus.—Dr. FURNISS also presented a patient who had a nephropexy in 1909, which had failed to give her relief. From October 1 to November 15, 1913, she had had port wine hematuria, which the cystoscope showed coming from both kidneys. In November she had a decapsulation of the left kidney. In 1912 the kidney wound opened and discharged urine for two months. Since that time the patient had had much pain in the region of the left kidney and at times some swelling. In April, 1914, cystoscopy showed marked redness around the left ureter. A solution of indigo-carmine injected intravenously came from the right ureter in three minutes and a half, but none was observed coming from the left. Radiographs showed an arrow-shaped calculus in the lower end of the left ureter. The calculus was removed by extraperitoneal operation. As the patient was not relieved of her symptoms and as the ureteral catheter could not be made to enter the ureter more than one and one-half inches, the left kidney was removed. It was most densely adherent and only one-fourth the natural size. The pathological and microscopical examinations showed chronic pyelonephritis with atrophy of the kidney. In the presence of an infected kidney that had completely lost its function, the operation that should have been done in the first place was a nephrectomy with excision of the ureter to a point below the calculus.

Sarcoma of the Metacarpal Bone: Extirpation and Replacement with Tibial Bone-Graft.—Dr. GEORGE H. SEMKEN presented patient, aged 19 years, a clerk by occupation, who came under observation on September 3, 1914. Seven months previously, he began to have pressure sensitiveness in the right hand. This remained the only symptom for five months; then a swelling appeared on the dorsum of the right hand about the distal half of the middle metacarpal bone. There had been a progressive increase in size of the mass. Pressure sensitiveness continued and he had occasional lancinating pain in the forearm. The history otherwise, was negative. Physical examination established the following: The dorsum of the right hand was the seat of a rounded, flattened swelling, about 3.0 to 3.5 cm. in diameter, beginning behind the articular surface of the head of the third metacarpal bone and extending proximally to about the middle of the bone. Laterally, the mass impinged upon the adjacent metacarpals. The overlying skin was raised by the flat convexity of the dorsum of the swelling but retained its normal color and free movability. Examination of the palm of the hand was negative. *X*-ray examination showed that the distal half of the third right metacarpal bone had been replaced by a rounded, cyst-like mass having a thin, bony shell and showing occasional bony septa. The line of the articular surface seemed well defined and intact. The distal end of the proximal half of the bone projected into the mass like two miniature church spires, and was united to the mass by a thickened periosteum. Operation was performed on September 7, 1914, under general anesthesia. Through a curved incision on the dorsum of the right hand, the affected bone was exposed. The tumor and the shaft were removed, but the carpal base was retained to act as an osteogenetic contact site for the intended bone transplant. The transplant was taken from the antero-internal surface of the tibia, and included periosteum, cortical and medullary bone substance. It was wedge-shaped in section. A secondary wedge made its basal end fit tightly into the retained base of the metacarpal bone; and the phalangeal end was rounded (cylindrically) to allow for the movement over it of the phalanx. This tibial bone-graft was placed in position, in a muscle bed formed by suturing the divided adductor pollicis to the interosseous muscle stump attached to the ring finger metacarpal; a few catgut sutures were placed over the graft to hold it in place. Finally, a small, free fat transplant was placed between the distal end of the bonegraft and the phalanx, to form a new joint. Healing was uneventful. An *x*-ray examination made seven weeks after operation, showed that the graft was in place, that it had retained its distinctive bone-markings and that a vigorous regeneration was taking place at the site of bony contact at the base. The free fat transplant, however, seemed to have been absorbed. The examination of the tumor showed it to be a giant-celled fibrosarcoma.

Epithelioma of Lips and Cheek: Radical Operation and Repair.—Dr. SEMKEN presented this patient, aged 57 years, a gardener by occupation, who had a small lesion on the upper lip seven years ago, which refused to heal and had to be excised surgically. Four years ago, in Montreal, a cautery operation was done to destroy a recurrence, but the growth soon reappeared, and it had continued to advance, though not rapidly, to its present extent. The appearance presented on July 7, 1914, when the patient came under observation, was as follows: Beginning at the right angle of the mouth, on the upper lip, an ulcerated, cauliflower growth extended in a widening area over the upper lip, reaching almost to the left ala nasi, then spread over the left cheek as it wound around the left corner of the mouth, and ended on the lower lip, about 2.0 cm. from the left angle. The mucous surface was involved to a slightly less extent than the external skin. The submaxillary lymph glands on both sides were moderately enlarged. On July 11, 1914, the submaxillary lymphatic and glandular structures of both sides were removed, and the left carotid packet of glands also. These wounds healed by first intention. It was interesting to note

that, in consequence of the ligation of the facial arteries of the two sides, evident starvation of the neoplasm occurred. There was a definite reduction in its size, and the discharge diminished. On July 18, 1914, the mass was excised under local anesthesia. The right angle of the mouth was incised, and from this starting point, the line of section proceeded widely from the margin of the growth. The cut mucous membrane was at once sutured to the cut skin margin, the purpose of this being to favor early closure of the wound surfaces, a minimum of scar tissue and an early restoration of relatively normal conditions in the surrounding tissues. Prompt healing occurred. The patient was then discharged from the hospital with instructions to return in about eight weeks for the plastic operation. The entire upper lip, the left half of the lower lip and a large part of the left cheek had been removed. The reparative procedures were begun on September 9, 1914. It was planned to take a large flap from the remaining skin and subcutaneous tissue of the left cheek and neck, properly shaped and with its pedicle above, and to swing this flap into the left cheek and lower lip defect. Part of this flap would necessarily present a raw surface to the mouth cavity; so the first procedure was to elevate that portion of the projected flap and to line it with a Thiersch skin graft. The raw surface left by its elevation was also covered with Thiersch grafts. The Thiersch-lined flap was then placed back to its old site, a small dressing of silver foil and gauze being interposed. These grafts healed well, and the major procedure could be undertaken ten days later. On September 19, 1914, under local anesthesia, the entire flap was raised; and after preparation of the edges of the defect, the flap was placed in its new site. The raw surface left by this maneuver was covered with Thiersch grafts. The reconstruction of the upper lip was done at the safe time, by the cutting of a long tongue-shaped flap from the right cheek and chin, with the pedicle above; by the undercutting and pushing back of the upper lip tissue at the extreme right; and by the placing of the tongue-shaped flap in position across the upper lip defect. The flap was cut in such manner, that the direction of the hair follicles was at right angles to the long axis of the flap; thus insuring the correct direction to the moustache that was to grow from the flap. The raw under surface of the flap was covered with Thiersch grafts. Prompt healing occurred, but an inadvertent movement during the removal of the sutures, caused a separation of the upper lip flap at its distal attachment and necessitated a secondary suture. Three subsequent operations were done to improve the cosmetic effect (smoothing-out procedures); and the appearance had been further improved through the growth of a moustache and a beard. The skin grafts within the mouth had withstood maceration and trauma very well. There had been no return of the carcinoma.

Dr. Robert H. M. Dawbarn said that since Dr. Semken had stated that his work was facilitated by using what he was good enough to call "Dr. Dawbarn's starvation method," and as it had perhaps also had something to do with the non-recurrence of the cancer up to the present time, this might be a fitting occasion upon which however briefly to comment on the starvation plan. He regretted to say that this had never had a fair trial, especially in sarcoma, for which rather than carcinoma it was especially fitted. One reason for this was that in many cases excision of the external carotid on one side only had been practised, with the inevitable result of wasted time. After an interval of a week or two for recuperation it should be repeated on the other side, for reasons that should be obvious to surgeons. At present the technique of the operation—which the speaker had now performed over 200 times—consisted in first tying off two branches—those to the larynx and to the tongue—and then without disturbing the body of the external carotid or its other branches, introducing, after ligating the external carotid close to its origin from the common into its lumen by a hypodermic syringe needle and glass syringe, about 6 c.c. of liquid paraffin, at a temperature of 120° F. which would solidify at 110° F. In this way any anastomosis reentering the field became impossible; and at one stroke twenty-odd ways of feeding the cancer were permanently cut off. It was wonderful how little blood normal flesh required to keep it alive—and how much a cancer demanded in order to keep growing. Everybody agreed that whatever the permanent outcome was, the first effect was a great relief to the patient, from shrinkage of the mass and lessening of tension. It would be noted that if one did not take the precaution to ligate those two branches first specified, the patient would have no control of voice or of tongue, because these arteries too would be paraffin-plugged. To allow a little more blood to reach normal tissues than by purely anomalous ways, it was in most cases wise to tie off, rather than paraffin-obstruct, the occipital artery, thus leaving its connection with branches of the subclavian free for circulation. At the time the starvation procedure won the Gross prize the technique was much more complex. Today it could be accomplished with ease in half the original time, perhaps ten to fifteen minutes, for leisurely work, if no enlarged lymphnodes requiring removal obstructed the field. Dr. Dawbarn said that one cannot be too careful to make sure by careful dissection that there was *a frank carotid bifurcation*, one branch of which immediately began giving off subdivisions, the other none at all in the neck. In this way the danger was obviated of making a blunder which, while following customary rules of technique, once led to the needless death of a patient at his hands. After he had tied a continuation of the common carotid which gave off branches at once, first finding that pressure upon it stopped the pulse of the facial and superficial temporal arteries (their regular tests), and the patient had been taken back to the ward, the anestheist commented upon the curious fact that the tying of the artery had been promptly followed by a pinhole contraction of the pupil on that side. Realizing that the internal, not the external carotid supplied the eye, and the internal, not the external carotid lay in contact with (upon) the sympathetic, it was practically certain that he had controlled the internal—and, to double the misfortune, had tied in the sympathetic with it; division of which in the neck contracts the pupil. At once the patient was hurried back to the operating table and the ligature in question was cut. A further dissection showed that he possessed the commonest anomaly in man, as to this artery (Deaver); namely, there was no external carotid, but the internal, on its way to supply brain and eye as usual, first gave off all the branches commonly supplied by the external carotid. (This same condition, *i.e.* absence or a merely rudimentary condition of the external carotid, its work being done by the internal, was the rule in dogs.) This patient never woke from his operation. This was a middle-aged man, and the anemia of the brain was fatal. This was true of 40 per cent. of middle-aged or elderly internal carotid ligations, from shock, or from subsequent brain softening (Wyeth). On the other hand there should not even be 1 per cent. of mortality from tying the external carotid, at any age, when uncomplicated by other operative measures.

Chronic Constipation.—Dr. James A. Corscaden read this paper. In this he advocated the treatment of chronic constipation by the use of a regime which made the patient take food and drink at frequent and absolutely regular intervals during the day and by giving a diet rich in cellulose. The schedule gave three meals a day and in addition, forty-eight ounces of water which was taken on arising, between the morning and noonday and noonday and evening meals, and on going to bed. The indications for this regime were based on the etiological findings in a series of 60 patients and by physiological principles based on experimental and direct observations. The results of this regime were sought for in 60 patients. Data were obtained in 43 of these, showing three failures, 22 complete successes, and 20 partial results. Of the latter cases nine were individuals who had distinct relapses all traceable to abrupt cessation of the regime. These were all subsequently cured. The remaining partially cured patients were having movements of the bowel without the use of cathartics and were divided into two types; those having a daily small unsatisfactory stool and those having constipation alternating with regularity. In all of the failures and in all of the partial results the cause of the negative result was the failure, complete or partial, of the patient to follow the regime or adopt the diet. This was due to antagonism or indifference on the part of the patient and lack of exactness and effort on the part of the physician. While some of the patients suffered from obstructions in the upper colon as shown by *x*-ray they all became regular. On the other hand those who failed to have regular movements did not reveal a single instance of interference with contraction of the upper colon.

Dr. Robert H. M. Dawbarn said there was nothing herein to which all could not give hearty assent. For

one point alone, he was glad to observe the order to drink a total of twelve gobletfuls of cool water during four intervals of the waking day. Insufficient water drinking was doubtless the chief factor in chronic constipation; and to make thirst the patients' guide was to choose the most treacherous of broken reeds upon which to lean. Given an excellent and active set of salivary glands, the mouth was seldom dry enough to excite a sense of thirst. For a poor creature afflicted by chronic constipation a bad salivary system was a real blessing—for she would then be forced to drink abundantly.

Metchnikoff had said that three chief causes lead to a lesser longevity than an average of 100 years for the human race! Of these, one cause was inherited or acquired syphilis, another alcoholism, and the third was the fact that Providence made us with pockets or pouches along the sides of the colon inviting stagnation of feces, although the central current might be free. Regarding one feature of constipation, causation, which he did not notice mentioned in the paper, a curious experience of his own in practice was not without its lesson for them. A certain middle-aged, sensible, non-hysterical lady, a clergyman's wife, came to him a few years ago for removal of ear-wax. Meanwhile, as she had mentioned always having had to make special efforts for bowel-relief, all her life, he counseled her very much along the lines of Dr. Corscaden's paper, rather than advising any drugs. Two years later on this lady called again, for the removal of ear-wax. This naturally brought up the former visit to his memory —and he asked her how her bowels were then behaving. After a moment's evident hesitation she replied, "I hate to tell you for fear you will be displeased, doctor; but since you ask, the truth is that a month or less after I left your office I became so tired of daily remembering all the things I ought and ought not to do, that I took a friend's advice (after first lapsing into my old way of using various kinds of proprietary pills, etc.). This advice was, to call upon a lady doctor who is a mind curist. Accordingly, I had a series of about ten treatments by her, three times weekly, and ever since then (nearly two years), I have been entirely well, paying no attention especially to rules of diet, and having a good evacuation daily."

I was naturally curious as to details, and my patient willingly gave them: "The lady doctor," she said, "had for her office one of our characteristic, old-fashioned, long and narrow parlors. At one end of this, with back to the light, she sat, at her desk. I was placed on a chair at the further end of this room, and she sat there and glowered at my stomach fixedly. It made me feel uncomfortable and creepy, there, at length, and I asked by way of saying something whether it was necessary to believe in order to succeed? 'Not at all,' was the doctor's answer. After some twenty minutes of this staring she said, 'That will do: that completes the first treatment.' The others were all exactly like it, and good results were soon noticeable." Dr. Dawbarn was sure that nobody here to-night believed for a moment that this quack doctor cured that woman, in the proper sense of the word. But she helped the patient to cure herself by autohypnotism, *i.e.* by concentrating her thoughts upon the derelict organs, leading soon and inevitably to improved abdominal circulation and peristalsis, because a greater percentage of nervous vital energy was drawn thereto than would otherwise have been the case. This being continued long enough to become a habit the cure was the natural result. If a girl while in the water closet had her mind upon a new spring bonnet instead of upon the business which brought her there, the result was naturally a poor one. He said he would never forget a remark during a lecture made to the class by that great neurologist, the late Dr. E. C. Seguin. He said that he was convinced that by continually thinking about a given normal organ or portion of the body anybody could with time render it less efficient in its work—in a word, diseased. If this was true, the converse of the proposition would seem equally so—that if a given organ (let us say the bowel) was out of order, by continual concentration of the attention upon it, improved innervation might result, with bettered function in consequence. It was a poor rule that would not work both ways.

A Preliminary Report on a Study of the Protective Ferments of the Blood by the Abderhalden Method, After the Transplantation of Organs.—Dr. CHARLES GOODMAN presented this report in which he recalled that at the recent meeting of the International Surgical Association, Carrel reiterated his former statements that he had met with considerable success in auto-transplantation, but that homotransplantation of an organ such as a kidney was only temporarily successful, the organ invariably showing degenerative changes within a few days. Lexer at the same time showed that he had succeeded in overcoming some of the biochemical reactions between his animals by a prolonged preliminary treatment of the host with tissues and blood taken from the donor. In the transplantation of parenchymatous organs the autolytic changes and eventual absorption might be due in part to defective venous drainage and the technique described was believed to minimize such injury. In transplanting the kidney of one dog to the neck of another, one might unite the renal artery end to side to the carotid, but the stroma of the renal vein should be placed end to end with the external jugular. This Dr. Goodman stated was a very important point, because it created immediate venous drainage for the transplant on account of the negative pressure in the jugular. Such drainage did not occur if the anastomosis was lateral. For an interval after an organ was transplanted it remained in a state of vasomotor paralysis, and was apt to become over-distended with blood on account of the insufficient venous drainage. Before employing and appreciating the value of end-to-end venous drainage, he had found it necessary to split the kidney capsule in order to prevent parenchymatous destruction by hypertension. On account of its accessibility and the ease with which degenerative changes could be recognized the thyroid had been selected for transplantation in this study. In two consecutive instances the thyroid was removed from the body and reimplanted in the same animal and the results were satisfactory, the thyroid tissue retaining its normal appearance and apparently its activity. In a series of homotransplants, although several of the animals lived for some time, the transplant invariably underwent degenerative changes with absorption.

From a series of fourteen specimens obtained at the Laboratory of Physiological Surgery of the New York University, it had been possible in eight instances to demonstrate the presence in the blood of a protective ferment capable of digesting tissue. The significance of the demonstration was problematical, but it might be an index of the susceptibility of the suprarenal body to insults occurring anywhere in the hemopoietic system. However, this might be, the Anderhalden reaction was positive in eight sera from seven dogs operated on as described. Tests with different substrata were being made to determine whether organs other than the suprarenal were sensitive to the thyroid transplant. It was thought that the biochemical differences which at present caused autolysis and prevented the use of transplants in applied surgery might be accomplished either by the application of Lexer's studies already referred to, or perhaps by the use of the *x*-rays or benzol, which in a measure controlled or modified lymphatic absorption. The use of such agents had been suggested by a study of John B. Murphy's publication in the *Journal of the American Medical Association*, May 9, 1914, in which he had shown that an organism did not react to a graft in the presence of general infection. He believed that the same factors which were engaged in fighting a general infection were also instrumental in causing similar behavior toward a transplant. Dr. Goodman said he hoped by demonstrating the presence of the specific ferments which followed transplantation to succeed in finding a method of controlling their activity. He illustrated the points brought out in the paper by a lantern slide demonstration.

Dr. JOHN WILLIAM DRAPER said he had had the pleasure of watching Dr. Goodman work at the Laboratory of Surgical Physiology. Aside from the technical details which were of import and interest, the most significant thing to him had been the biological side of his work. Dr. Goodman had had an opportunity to spend some time working under Abderhalden in his laboratory in Germany, and in the author's postoperative studies of the blood of the operated animals the Abderhalden technique had been followed to the very letter. The provisional finding which pointed to a reaction in the blood to suprarenal tissue after certain forms of thyroid transplantation would appear to suggest, Dr. Draper said, some possible relation between these two glands.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held October 6, 1914.

THE PRESIDENT, DR. SMITH ELY JELLIFFE, IN THE CHAIR.

Double Cervical Rib; Nerve Symptoms; Surgical Removal.—Drs. S. P. GOODHART and ALFRED S. TAYLOR presented this case. The patient was a woman, thirty years old, whose history, both family and personal, was entirely negative from a neuropathological point of view. Symptoms referable to the cervical ribs dated apparently from the patient's eighth year, when she began to suffer from pains in the left shoulder radiating down the arm, and the entire left upper extremity would become paroxysmally numb. There was also a gradual development of an indefinite sense of discomfort about the left shoulder and a protrusion of the left shoulderblade, which, when pressed upon, gave rise to varying degrees of pain and numbness extending through the arm. These symptoms persisted, and in the course of a few years there was added a certain inability to properly use the left index finger, noticed particularly in playing the piano, and gradually a lack of dexterity of the left hand. During her eighteenth year she noticed that certain movements of the arm, for example, arranging her clothing necessitating placing the arm behind her, caused flexor spasm of the muscles of the forearm and hand. At this time there was no weakness nor wasting of the muscles. When the patient was twenty-three years old she observed weakness in the grasp and in the finer movements of the left hand, followed by progressive atrophy of the small hand muscles, both the thenar and hypothenar surfaces being involved. Soon afterward a coldness of the left upper extremity, particularly from the elbow to the finger tips, was at times subjectively felt and could be objectively demonstrated. The patient came to Dr. Goodhart in 1904 with the diagnosis of progressive muscular atrophy. At that time his examination revealed areas of hypesthesia and hyperalgesia irregularly distributed over the left forearm and hand. These areas varied and finally disappeared, leaving as the only sensory disturbance an area of hypesthesia for all forms of sensation in that part of the forearm and hand corresponding to the inner cord of the brachial plexus, particularly the ulnar distribution. At this time the left hand presented an appearance of the typical *main en griffe*, and some atrophy of the pectoral muscles was noted. Further physical examination revealed osseous tumors in each supraclavicular space, which were recognized as cervical ribs. The one on the left side was found two inches outside of the sternal insertion of the sternocleidomastoid muscle, extending vertically upward two inches from the upper clavicular border. On the right side a far smaller eminence was found in about the same position. The *x*-rays disclosed scoliosis extending from the sixth cervical to the fifth dorsal, with the convexity to the left side, and with a compensatory convexity below. Bilateral cervical ribs were seen attached to the bodies of the seventh cervical vertebræ, articulating at their distal ends with a facet from the upper border of the first dorsal ribs. On the left side the supernumerary rib measured about one and three-quarter inches; the right one, about two inches in length. About 1907 the patient began to observe a weakness in the right index finger and a certain lack of dexterity in executing finer movements with the right hand; slight occasional numbness of the right thumb was also complained of. Thus, involvement of the brachial plexus on the right side developed. Within the next few months numbness of the entire right leg and pains in the calf muscles were experienced by the patient, and Dr. Goodhart was able to detect at times a slight but manifest weakness in the flexors of the toes of the right foot, but there were no secondary nor electrical changes. In May, 1908, the patient submitted to an operation for the removal of both false ribs, which was performed by Dr. Alfred S. Taylor. Upon exposure it was seen that the subclavian artery crossed the first rib anteriorly and below the distal end of the cervical rib, the roots of the plexus lying over the false rib, as had previously been determined by palpation. The eighth cervical and first dorsal roots were undergoing the greatest tension and pressure. This coincided with the clinical symptoms. The relation of the structures was about the same on both sides, and the upper roots were so situated as to be but little compressed. Immediately following the operation there was paralysis of nearly all the muscles and the sensory surfaces supplied by the plexus on both sides. In the course of a week motion and sensation began to return, and the improvement, though slow, was constant. About one year after the operation there was still considerable atrophy and very slight sensory changes over the inner surface of the forearm. At the present time, about six years after the operation, there was marked improvement in the muscle supply.

Dr. RICHARD B. KRUNA suggested that the persisting deformity of the hand and arm might be improved by a systematic course of exercises of the involved muscles and nerve tracts.

Dr. CHARLES A. ELSBERG, in reply to an inquiry as to whether he thought this patient might be benefited by further operative interference, said her symptoms were incomplete and there was no reason to think there had been sufficient injury to the branches of the plexus to justify an operation which would necessitate a complete division of the nerve cords and subsequent suture. Through reeducation and systematic exercises, as suggested by Dr. Kruna, we might get other nerves to take up the impaired muscles.

Spinal Hematomyelia of the Hemiplegic Type.—Drs. FREDERICK TILNEY and C. L. NICHOLS of Brooklyn presented this case. The patient was a printer, twenty-eight years old, who was admitted to the Coney Island Hospital on June 18, 1914, with the history that shortly before admission, while diving in shallow water, his foot slipped and he fell into the water almost perpendicularly. He did not recall whether he struck the sandy bottom on his head, neck, or back, but thought that it was on the vertex, posteriorly. He had to be dragged from the water and was found to be suffering from a complete paralysis of the right upper and lower extremities, and an awkwardness in the use of the limbs on the opposite side. There had been no loss of consciousness and he was perfectly oriented. His head was numb and the whole body felt bruised and sore. The pain was most severe over the right shoulder, extending down the arm and forearm. There were no spasmodic movements in this area. When the patient was examined several hours after the injury he still complained of the sensation of having been bruised, especially over the right clavicle and upper chest. He was exceedingly sensitive from a sharply defined point at the sternoclavicular articulation outward to nearly the tip of the shoulder. The right pupil was smaller than the left; both were symmetrical and responded to light and accommodation. The right side of the neck was moved with great reluctance, and posteriorly there was a certain amount of rigidity. The right side of the chest was less mobile than the left, and the breathing sounds over the former were diminished. The heart's action was slow and regular and the sounds of good character. The pulse was of fair quality and volume. The abdomen showed no abnormalities. No reflexes could be elicited on the right side, and sensation was absent, with the exception of variable areas of response to pin prick. The field of vision was undisturbed. The fundus showed slight congestion of the nerve; the margin was not well defined, and the vessels were slightly engorged, evidencing some pressure. The hearing was affected on both sides. On examination on June 25, one week later, the anisocoria was still more apparent, the left pupil being larger than normal and reacting promptly, while the right was smaller and sluggish. The patient was placed on a water bed for two weeks, during which time the soreness gradually cleared up and the paralysis improved. He was then permitted to sit up, supported by pillows, and to use a mattress bed. Two weeks later he was allowed to sit in a chair and ten days after that he was able to walk. He remained in the hospital a month and a half. On the first day after his discharge he had an agonizing pain on the right side of the head over an area extending from the forehead along the vertex in the median line to the occiput. This persisted for two hours, gradually increasing in severity and then diminishing slowly after the application of cold compresses. A similar attack, less severe, followed a week later. After the patient had been seated for any length of time he became stiff in the right hip, and on arising had a dull pain extending from the lower part of the spine forward into the right groin. This symptom had been noticed irregularly, averaging once a day, since he had been permitted to sit erect in a chair at the hospital. He also complained of a similar pain extending from the cervical spine to the right shoulder. There were no urinary symptoms. The bowels had moved regularly ever since the accident. Examination at the present

time showed a flaccid paralysis of the right upper extremity and a spastic paralysis of the right lower extremity. The tendon reflexes on this side were greater than those on the left, while the abdominal, epigastric, and cremasteric reflexes were absent. The latter were present on the left side. The Babinski was positive on the right side, and there was permanent clonus in the ankle. A peculiar circumstance in connection with the case was that in eliciting the triceps reflex on the right side, percussion on either the tendon or the muscle produced flexion of the forearm instead of extension. The radiograph showed a fracture of the sixth cervical vertebra.

Spinal Hematomyelia; Brown-Séquard Paralysis.—Drs. TILNEY and NICHOLS also presented this case. The patient was a boy of twenty, an electrician, who was admitted to the Kings County Hospital on November 10, 1913, with the history that just previous to admission, while climbing a tree, the branch broke, and he fell a distance of about ten feet, first striking upon his buttocks on a branch below, and then falling to the ground on his chest. He lay flat on his face, without losing consciousness, the fingers of both hands contracted spasmodically. None of the extremities could be moved voluntarily, and he felt as though a current of electricity had passed through him, leaving the body charged from the shoulders down. The right lower extremity seemed to contain a tremendous pressure, and a tingling sensation passed up the left leg, across the pelvis and down the other limb. The direction did not change. Physical examination showed an apparently healthy and well developed adult, rather nervous, with a slight tremor of the hands. The pupils were equal, and reacted naturally. The pulse was regular and of good volume. The heart sounds were normal. The respiration was chiefly abdominal, the chest moving very little. The arms could be moved, though very slowly and with great difficulty. The fingers were held in a position of partial flexion, with no power to either flex or extend them. The knee-jerk was absent on the right side; present on the left. The Babinski could not be elicited. The toes of the right foot were red; those of the other pale, and the surface temperature of the left lower extremity was diminished. There was an absence of the cremasteric reflex. There were marked sensory changes. There was tactile anesthesia in both lower extremities and in the trunk up to the second interspace. Pain sense was absent in the left leg and as far up as the third rib, but present over a corresponding area on the opposite half of the body, where it was apparently hyperacute. The temperature discrimination was entirely absent on the left side to a level a little below the clavicle, but was present on the right side, although the response to heat was not as good as to cold. There were sticking pains in the right leg, and the patient felt as though there was a strap around it and another around the shoulders, each being tightened in an opposite direction. There were fibrillary tremors on the left side. Priapism was present during the examination. Catheterization showed no evidence of hematuria. One month later the patient had slight power of flexion of the left fingers. Sensation was unchanged. The pupils reacted promptly, but were unequal. The patellar reflex on the right side was exaggerated. One week later there was an involuntary urination. Up to that time catheterization had been necessary, but from that time on the control of the bladder was normal. The lesion in this case was located in the upper cervical region. The radiographs demonstrated no fracture nor dislocation.

Spinal Hematomyelia of the Paraplegic Type.—Drs. TILNEY and NICHOLS presented this third case. The patient was a Russian tailor, 34 years old, who came to the Vanderbilt Clinic on September 16, 1914, complaining of inability to walk properly, with pain in the back when seated, swelling and coldness of the feet and lack of control of the bladder. The family, as well as his previous history, was negative. Nine months ago, in an attempt to escape from a burning building, the patient either fell or jumped from a fire escape, a distance of two stories. He was picked up in an unconscious state and removed to the Gouverneur Hospital. He remained unconscious for two hours—perhaps longer—and on recovering his senses he was unable to move either lower extremity and had retention of urine. He remained in the hospital for six weeks, with slight improvement. He was then taken to the Beth Israel Hospital, where he remained three months and where some operation was done. Following this his condition improved and he regained some power to move his legs. He was now able to walk, with some difficulty. Examination at the present time showed normal cranial nerves and normal reflexes, with the exception of those at the patella and ankle, which were exaggerated. The station was unsteady and the gait spastic. Motor power in both extremities was defective, with some atrophy of the muscles. There was a fine tremor of the hands and tongue. There was an area of anesthesia over the left gluteal region.

Dr. FREDERICK TILNEY who had seen the two cases of Dr. Nichols in the early stages, said that in both instances he had concluded that the condition was due to hemorrhage into the cord. In the second case, that showing the Brown-Sequard syndrome, the question of an operation was considered by Dr. Arthur C. Brush, who advised against it. The improvement in this case was so marked during the first three months after the injury that further delay was advised, and the patient was now able to walk, whereas when he was brought into the hospital he was completely paralyzed. In the first case, the patient with hemiplegia following a diving injury, the radiograph showed a fracture of the sixth cervical vertebra, but this was of such a character that the symptoms seemed to be due to hematomyelia rather than to a cerebral injury or a crushing of the cord. In this case an expectant plan of treatment was also followed, and the patient had improved steadily. One of the reasons why these cases were shown here to-night, Dr. Tilney said, was to get an expression of opinion from the members as to whether early operative interference was advisable in dealing with injuries of this character.

Dr. WILLIAM M. LESZYNSKY said that in cases of traumatic lesions of the cord, of which he had seen a large number in hospital practice, the question of operation usually came up for discussion, and in answering it he had been largely guided by the clinical manifestations. If either by palpation or the *x*-ray it could be shown that we were dealing with a fracture dislocation producing crushing of the cord, as evidenced by complete motor and sensory paralysis and abolition of reflexes below the lesion. an operation was inadvisable. When blood is found in the cerebrospinal fluid, the hemorrhage is usually subdural. When the cerebrospinal fluid is clear, as in hematomyelia, operation is not indicated. In many of these cases, Dr. Leszynsky said, the early residual symptoms often became permanent, their severity depending upon the amount of damage done to the cord. It was impossible to give a positive prognosis as to the ultimate outcome.

Dr. BENJAMIN ROSENBLUTH said the first case presented by Dr. Nichols he had seen at the Beth Israel Hospital; the man had been previously treated at the Gouverneur Hospital and was brought in with a complete flaccid paralysis of the lower extremities, anesthesia, loss of reflexes and localized pain over the spine. He was put in plaster, but this proved so painful that it had to be taken off. Several radiographs were taken with no definite findings. A localized injury involving the body of the vertebra and transverse process and possibly the cauda equina was suspected, and when the spinal canal was opened over the region of the cauda the nerves were found to be pushed about in all directions and there was a large collection of cerebrospinal fluid. This pressure was relieved and the man made a good recovery so far as motility was concerned, but he still had an area of anesthesia over the thighs. Dr. Rosenbluth said this was the fourth case of injury of the cauda equina that had come under his observation, and the result of the operation was the most encouraging he had seen.

Dr. J. F. TERRIBERRY, in reply to Dr. Tilney, said that in cases where one could be fairly certain that there was hemorrhage within the cord, little could be expected from operative interference. This could perhaps be determined by the *x*-ray, together with the clinical history. In the two cases shown by Drs. Tilney and Nichols the history clearly indicated a hemorrhage into the cord itself, and under those conditions no benefit could be derived from an operation. The spinal cord is a very sensitive organ as we all know, and any injury to it might be aggravated by operative interference. These cases, as a rule, did much better under proper general care, with subsequent reeducation of the lost muscular function if the residual symptoms demanded it. The fact should be borne in mind that this loss of function was sometimes attributable to a stiffening of the joints of the hands and fingers, and it was only with care and perseverance that one could get the most out of these cases.

A Case for Diagnosis.—Drs. A. Skversky and Smith Ely Jelliffe reported a case of a child, seven and a half years old, of normal birth, who sat, talked, and walked at the proper ages, and appeared to develop normally. She had measles at the age of three years, with an uneventful recovery. Six months later she was said to have had a high fever one night, but no residuals followed. Five weeks after this, without any premonitory symptoms and without convulsions, she had a sudden loss of power on the left side of the body involving both extremities and the face, without speech disorder. Two weeks later, according to the mother's description, she had epileptiform seizures, apparently Jacksonian, for they began in the left lower extremity, ascending, involving the upper extremity and face, and terminating in a generalized convulsion. This occurred only once, and following this her hemiplegia was said to have cleared and she was perfectly well for three months, when she began to have irregular involuntary movements of the extremities on the left side, accompanied by some difficulty in walking. This had been becoming slowly but progressively worse. For the past year she had headaches at irregular intervals, but excruciating, and lately they had become more continuous and dull, usually localized in the right frontal region. She had also complained somewhat of dizziness. There was occasional nausea, but no history of vomiting. There has been no difficulty with vision or hearing. The mother claimed that the child's speech had always been somewhat drawling and monotonous. She was rather bright, but had received no schooling and became emotional by slight stimulation. For the past month she had had some difficulty with bladder control, with occasional incontinence of urine. When the patient was brought to the Post-Graduate Hospital, about a month ago, her chief complaint was difficulty in walking. Examination showed a well developed and nourished child. Her mental level, according to the Binet-Simon rule, was only a little less than a year below her age, and she was therefore not feeble-minded. There was marked ataxia, with mild left hemiparesis. The more important positive neurological findings were as follows: The head was usually inclined towards the right, and the face tilted towards the left. Vision was normal, but the fundi presented double optic neuritis, more marked on the right side. At rest, there was slight ptosis on the right side, and also weakness of the right internal rectus. No nystagmus. The reactions were fairly normal. The fifth nerve was intact: there was slight facial palsy on the left side when crying. Hearing was normal. The speech was drawling in character: swallowing normal. The left upper extremity showed no atrophy nor hypertrophy, but marked hypotonicity and slightly decreased muscular power. The reflexes were present. There was marked incoordination, often resembling a very coarse intention tremor. There was marked adiadochocinesia: The stereognostic sense was intact: there was some dissociation of motion and position and also temperature sense; there was general hyperesthesia, apparently emotional, with contradictory replies and lack of proper cooperation. The right upper extremity showed a slight incoordination on volition. The abdominal and epigastric reflexes were present, with marked asynergia of the trunk. The left lower extremity presented a similar picture to the upper, but more pronounced. There was hypotonicity and decreased muscular power. The patellar and Achilles reflexes were present, but not exaggerated: no Babinski nor other extensor responses. On a few occasions, a double exhaustible ankle clonus was obtained. There was marked impairment of synergistic sense, as well as definite ataxia, not increased on closure of the eyes. The superficial reflexes and sensory symptoms were similar to those in the upper extremity, occasionally dissociated, but contradictory. The authors stated it was evident from the symptomatology present in this case that one of the factors they were dealing with was that of increased intracranial pressure, as shown by double optic neuritis, headache and vertigo, and, more recently, somnolence. Syphilis was ruled out by negative blood and spinal fluid examinations and by the family history. There then remained the possibility of neoplasm, cysts or internal hydrocephalus. If we assumed that we were dealing with a neoplasm, which was quite likely, because the process had been a slowly progressive one, the localization in this case became a rather difficult and uncertain one. There was a good deal of evidence suggestive of chronic cerebellar disease, as shown by the vertigo, the markedly ataxic gait, asynergia on voluntary movement, and mild hemiparesis, together with a definite adiadochocinesia and unaltered plantar and inconstant deep reflexes. There was, however, no nystagmus. As to cerebellopontine angle involvement, there was of course a mild facial palsy, but no disturbance of hearing, and it seemed rather unlikely that an extracerebellar lesion in this region, which was usually of auditory nerve origin, should not produce some disturbance of hearing. In view of the very early appearance of Jacksonian convulsions—two weeks following the initial hemiplegia—it was difficult to rule out a motor cortex disturbance, and with the few definite localizing signs, it was suggestive of a supratentorial process, probably subcortical. It was therefore quite likely that a progressive lesion in the post-frontal region would cause contiguous pressure phenomena, and in addition interfere with the fronto-cerebellar tracts, giving the signs simulating cerebellar disease. The optic neuritis, generally late in onset, would fit in here. The convulsions might be explained by a lesion in the vermis, which usually gave rise to so-called cerebellar fits, and therefore completed the picture of a distinct cerebellar affair. Similarly, the post-parietal area so intimately associated with cerebellar functions might easily account for nearby pressure signs, but the usual sensory disturbances were lacking: also the stereognostic and visual functions were intact. The child had often displayed choreoathetoid movements on the affected side, increased on exertion: this, with her increased emotional reaction to external stimuli would suggest a thalamic lesion, but the sensory symptoms, especially the subjective paroxysmal pains, heat and cold, and the hemianesthesia were absent. If only the posterior end of the thalamis be involved, superior cerebellar peduncle disturbance would answer well. As to the nature of the lesion, if we realized that the disease was probably of three and a half years duration in a child seven and a half years old, it was difficult to ascribe it to the characteristic ones, namely, sarcoma, glioma, tuberculosis, cyst, etc. The optic neuritis was apparently of recent onset, because the vision was fairly intact. Tuberculoma was rendered improbable by the absence of signs elsewhere, while sarcoma or glioma should have done more damage by this time unless there be a recession, with cyst formation. Internal hydrocephalus could be fairly ruled out by the absence of sufficient mental impairment, lack of motor tract disturbance and gross appearance of the head. The most likely lesion would be the relatively benign endothelioma.

Dr. Leszynsky said the history of the case seemed to indicate an encephalitic process to begin with. What the condition was now he did not know, but the symptoms pointed to a cerebellar lesion.

Dr. Tilney said that from the confusing symptoms, it was difficult to decide upon any particular localization. Still, the ataxia pointed quite definitely to a cerebellar lesion, and as we knew that that part of the brain is so frequently affected in children, he would be inclined to ascribe the symptoms to a lesion involving the dentate nucleus on the left side.

Dr. S. P. Goodhart said that in the absence of nystagmus, he was inclined to accept the assumption of Dr. Tilney, and he thought that a post-frontal right-sided lesion could be positively ruled out. In a hypophysial tumor it was not uncommon to find the field of vision unaffected.

Dr. Rosenbluth, who had previously seen this patient at the Beth Israel Hospital, said that while the history he obtained from the mother at that time was not very clear, it pointed to a meningitis in infancy, and the convulsions seemed to be post-encephalitic, apparently of the motor cortex type. The eyes at that time gave negative findings. He regarded the case as one of left cerebral hemiplegia, with post-frontal sensory disturbances.

Dr. Terriberry thought the symptoms pointed to a preceding inflammatory process, and gradually progressing from an irritative into a compressive condition. The symptoms seemed to indicate that the trouble, at present, was confined to the sensory apparatus. It was impossible to trace these symptoms to a small focus. We probably had to deal here with what was at first a rather widely distributed irritation which had now become restricted to a basal situation fairly well forward. He was not inclined to believe that we had to deal with a neoplasm. Possibly there was an internal hydrocephalus as a part of the picture.

Dr. Leszynsky thought the authors had scarcely been justified in ruling out an internal hydrocephalus, while a subtentorial process, which they favored, would

probably have given rise to more pronounced papillitis. In all probability, the speaker said, the child had an encephalitic process which produced the original symptoms; namely, the convulsions and subsequent paralysis.

Dr. M. NEUSTAEDTER thought the vague history of fever obtained in this case could practically be disregarded. It rested simply on a statement made by the child's mother and probably had no bearing on the case.

Specific Lesion Involving the Thalamus.—Dr. SMITH ELY JELLIFFE reported the case of a married woman, 32 years old, the mother of three children, aged respectively, nine, seven, and two and a half years. The patient's history dated back to March, 1913, when she began to suffer from pain on the left side of the body and the left arm and hand, with numbness, and pain in the neck on the same side. These pains were rather severe, and of a sharp, shooting character, and have been more or less constant from that time on. Following this, there was a slowly progressive numbness and tingling, with a sense of insecurity on the left side of the body and face, and she noticed that she began to drop objects that she held in her left hand. There was also a slight irregular tremor of the left hand when she began to use it. Examination showed a definite impairment of epicritic sensibility in the hands and feet and a loss of stereognostic sense. The reflexes were increased on both sides, but not more marked on one side than the other. There was no Babinski; no ankle clonus. There was a definite loss of ability to pronate and supinate on the left side, without impairment of muscular power (adiadochocinesia). There was no interlacing of the color fields, but the eye charts indicated the onset of a gradual bitemporal field contraction for all colors, premonitory to a bitemporal hemianopsia. The Wassermann was originally negative, but under a provocative neosalvarsan injection it became double plus; subsequently it again was negative. The *x*-ray showed no changes in the sella turcica. The patient complained of a crackling noise in the left ear. During the earlier stage of this patient's illness, Dr. Jelliffe said, there had been a great deal of emotional hyperactivity, with asthenia, which had led to a previous diagnosis of hysteria.

Dr. LOUIS CASAMAJOR said the sensory and motor symptoms in this case led him to think of a thalamic lesion. He could recall instances where for a long time such a lesion gave rise to symptoms which were regarded as functional before its organic character was recognized. This assumption of a thalamic lesion, however, was not in accord with a bitemporal hemianopsia, as it was difficult to conceive how a single lesion could reach from the posterior part of the chiasm upwards and not involve the pyramidal tracts.

Dr. TERRIBERRY said the eye chart shown by Dr. Jelliffe did not indicate a bitemporal hemianopsia: it only showed a concentric contraction of the visual fields. The symptoms in this case reminded him of one that recently came under his observation in which he made a diagnosis of hysteria which subsequent events proved to be correct.

Dr. TILNEY said that with the bitemporal hemianopsia eliminated, he thought the symptoms pointed to a thalamic lesion.

Dr. WALTER TIMME thought the symptoms indicated a thalamic lesion. It had lately been reported that the subthalamic lesions had some effect on bladder control, and this fact would suffice to indicate that the lesion producing the syndrome shown by the patient was located in the hypothalamus.

Dr. ROSENBLUTH suggested a multiple sclerosis with unusual symptoms, most likely a luetic process. In such a case we might have to deal with a thalamic lesion, as cases he had seen with multiple sclerosis symptoms with sudden onset had shown thalamic lesions postmortem.

Dr. GOODHART thought the indications were in favor of a vascular lesion of specific origin.

Dr. JELLIFFE said the suggestion made by Dr. Rosenbluth was interesting in view of the fact that the Wassermann test was positive in some cases of multiple sclerosis. Personally, he had no doubt that we were dealing here with an organic lesion. These thalamic cases were not infrequently looked upon as functional because of the fact that the symptoms were purely sensory. We had here a beginning thalamic syndrome which was practically never found in hysterical states. This patient further had a sinus disturbance on the right side which rhinologists diagnosed as specific or tuberculous.

New Clinical Instruments for Measuring Muscle Strength and Tendon Reflex Threshold.—Dr. FREDERICK TILNEY of Brooklyn read a paper on this subject, with lantern-slide illustrations, and showed two new clinical instruments of precision for measuring muscle strength and tendon reflex threshold.

Dr. LOUIS CASAMAJOR said that these instruments of precision devised by Dr. Tilney were a step in the direction of placing neurology on a more exact scientific plane. The dynamometer he had found of extreme value in testing the strength of certain groups of muscles, particularly in cases of anterior poliomyelitis and in watching the return of the muscles function in traumatic brachial palsy. With this instrument we could detect the earliest return of function and could base our prognosis upon exact scientific measurement rather than upon pure guesswork. He had also found it of value in drop foot and other conditions, and it had made a strong impression upon him as being something more accurate than any instrument of the kind that we had had before.

Dr. TIMME said the stereopticon pictures of the tendon reflexes shown by Dr. Tilney were an excellent illustration of the accuracy of this instrument, as compared with the older methods. Instead of adding to the history of a case that the "reflex was still deficient" or an equally unsatisfactory expression, we had here an instrument which gave us in exact terms the amount of improvement or otherwise that had taken place.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

AT a stated meeting held December 10 Drs. ALLEN J. SMITH and ROBERT A. KEILTY demonstrated a specimen of "Chorionepithelioma: Diagnosis from Uterine Scrapings, with Confirmation at Operation." The patient was a woman supposed to be pregnant and in whom uterine hemorrhage led to curettage. From examination of the scrapings a diagnosis of hydatidiform mole was made. With the recurrence of hemorrhage hysterotomy was performed, with the removal of more tissue, which histological examination now demonstrated to be of the nature of chorionepithelioma. Further bleeding taking place, the uterus and appendages were removed, and the presence of the actual growth established.

Drs. D. RIVAS and BALDWIN LUCKE demonstrated "Eggs of Hookworm and Fascilopsis Buski." The specimens came from Hindus, whose stools were examined because they came from Calcutta, and in one ova of Necator Americanus were found, and in another ova of the Fasciolopsis in addition. Apart from eosinophilia, more marked in the case of double infestation, there were no clinical symptoms of the presence of the parasites.

Dr. D. J. MCCARTHY demonstrated "A Tumor of the Cerebellum." The specimen came from a tuberculous subject and the new growth was apparently encapsulated and readily isolable, suggesting its surgical removability, but histological examination showed round-cell infiltration of adjacent tissue. Giant-cells were absent, but tubercle bacilli were present.

Dr. ROBERT N. WILLSON demonstrated a fetus of five or six weeks' development, showing the heart and the blood-vessels and sex-differentiation.

Dr. WILLSON also presented a number of specimens showing intensely calcareous brachial, radial, and ulnar arteries from a man fifty-four years old.

Drs. ROBERT A. KEILTY and ALLEN J. SMITH presented a communication entitled "Intestinal Stasis, Bands and Kinks and Membranes from a Study of One Hundred Autopsies," illustrated by lantern slides. He divided these formations into congenital or embryological, inflammatory, and developmental-hypertrophic, and he showed how they operated under different conditions.

Drs. JOHN A. KOZMER and A. STRICKLER presented a communication entitled "Complement-fixation in Parasitic Skin-diseases." They presented the results of studies with ringworm of the scalp and favus. They obtained complement-fixation reactions in 78 per cent. of the cases, and while they found that both forms of disease reacted similarly, they were unable to obtain similar reactions in the presence of other varieties of disease of the skin and in cases of syphilis. Dr. Strickler related a number of successful therapeutic applications of vaccines in the treatment of ringworm and favus.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

FEAR AND CONVENTIONALITY. By ELSIE CLEWS PARSONS. Cloth; 234 pages; price $1.50 net. Published by G. P. Putnam's Sons.

Therapeutic Hints.

Treatment of Tuberculosis of the Larynx.—H. Lambert Lack states that the first aim is to improve the general condition of the patient. Tuberculin injections and local treatment may be carried out simultaneously. Strict silence should be enforced, the patient being instructed to write rather than speak, and all useless cough should be prevented. The local treatment varies according to the lesions. Tuberculous tumors should be removed with cutting forceps or curette, or destroyed by cauterizing or caustics under local anesthesia. If it is impossible to deal with them in this way the patient may be anesthetized and the growths removed, preferably with the cautery, by the aid of suspension laryngoscopy. A superficial ulcer of the vocal cord may be treated in a similar way. If there are fleshy granulations they should be lightly curetted, and then the base of the ulcer thoroughly rubbed with chromic acid or nitrate of silver fused on a probe. In milder cases, or as a subsequent application to an ulcer which is slow in healing, lactic acid may be applied. It is best to apply the undiluted acid under local anesthesia. Fleshy granulations on the vocal cords should also be curetted or picked off with cutting forceps and subsequently cauterized or caustics may be applied. When there is edematous infiltration of the arytenoids and epiglottis without ulceration great care must be exercised. If the disease in the lungs is early or seems arrested and the patient's general condition is good, the larynx should be cauterized under local anesthesia. Three or four deep punctures may be made with the sharp point of a galvanocautery at intervals of not less than ten or fourteen days. Similar treatment may be carried out when there is ulceration of the arytenoids or of the epiglottis, if all other circumstances are favorable. Caustics must never be indiscriminately applied. If the patient's resisting power is not good they merely cause rapid spread of the ulceration, weakened infiltrated tissues breaking down without any tendency to heal. If the epiglottis is edematous and ulcerated and is apparently the only part affected it should be removed under cocaine with the punch forceps. In advanced cases in which the disease involves the arytenoids and epiglottis palliative measures must be directed against the dysphagia and the pain. Ulceration or edema of the epiglottis should be relieved.—*Clinical Journal.*

Insomnia and Indigestion.—T. J. Kelly finds that in the large group of cases of insomnia caused by dyspepsia, relief may be effected by stimulating the gastric functions by the use of a non-fluid diet and by giving before each meal a simple bitter alkaline mixture as:

℞ Sodium bicarbonate, gr. xx.
Tincture of nux vomica, mx.
Tincture of ginger, mxx.
Compound infusion of gentian, ad ℥j.

In the sthenic type of indigestion, in which the hyperacidity is the chief disturbing factor, a sedative mixture should be given before each meal:

℞ Tincture of belladonna,
Tincture of ōpium, āā mx.
Solution of suprarenal extract, mx.
Spirit of peppermint, ad ℥j.

This is to be taken in two tablespoonfuls of water a quarter of an hour before meals.—*Dublin Journal of Medical Science.*

SCIENTIFIC KNOWLEDGE LOGICALLY APPLIED TO ACUTE GONORRHEA IN THE MALE URETHRA.*

BY G. S. PETERKIN, M.D., F.A.C.S.,
SEATTLE, WASHINGTON.

SCIENCE is defined as knowledge, the result of observation, experimentation, and reasoning. Scientific knowledge logically applied signifies employment of theories of action in so far as they will produce practical results. In the vernacular of the laity, it is the application of common sense to the object undertaken. The first principle in the employment of common sense is the development of the ability to see things as they are and tell of them as they appear, not as one would like to have them. The medical profession would like to have a panacea in the form of a drug or specific treatment for gonorrhea, *but there is none*, and what is more to the point, the treatment of the disease will be more successful if the idea of a panacea is given up and the disease in each case studied, then treated.

The things we have to observe, experiment with and reason on in the subject under discussion may be placed under four headings: (1) the gonococcus, (2) the male urethra, (3) the host or individual, (4) the various therapeutic agents. The next step is to classify under these headings the results of scientific research in the form of facts essential to our main subject so that there can be no question that the final deductions are correct. Logic demands this, yet the writer realizes the danger of making the introduction appear trite and the article a rehash. So to obviate this and save time, the essential facts regarding the gonococcus, the urethra, the host, and the various therapeutic agents are tabulated and placed at the end of the article to be used as reference or read in detail, according to the reader's understanding of the arguments as presented.

Summed up, the essential facts tabulated give us the following premises: (a) Gonorrhea is an inflammation. (b) The causes of inflammation are bacterial (here, the gonococcus), traumatic, chemical, and nervous. (c) The results of the causes of inflammation to the host are heat, pain, redness, and swelling of the area attacked (the urethra). (d) The inflammation occurs in an area the anatomical character and physiological function of which must be recognized in treating the disease. (e) The host overcomes bacterial infection, effects of traumatism, etc., by leucocytosis, chemotaxis, and the lysins of the serum. (f) Leucocytosis, chemotaxis, and the lysins are dependent for their efficiency upon the reduction of the congestion and increased activity of the circulation in the area affected. (g) The mandates of the laws of nature brook no sentimental interference but demand assistance in attaining their object. So, in substance, the general principle of action that must govern all therapeutic measures is to obtain scientific knowledge, through reasoning impersonally and without sentiment on the essential facts; then to employ same to aid and not to oppose the natural laws, physiological and pathological, which control or eradicate this disease.

Therapeutic Measures.—Treatment of gonorrhea to be successful, must have for its fundamental object the relief of congestion in the area affected. This necessarily includes the stimulation of circulation, the destruction of the invading bacteria, etc. This being true, all causes and conditions tending to increase congestion or retard free circulation in the part invaded must be clearly enumerated, so as to obtain through logical reasoning a means of systematically avoiding or overcoming same. Briefly, these causes and conditions may be summed up in the one word, *irritation*, which may be either mechanical (including traumatic and nervous), chemical, or bacterial.

Mechanical Irritation.—The essential facts concerning mechanical irritation, and from which deductions as to the most successful method of treatment must be made for the relief of the peculiar inflammation known as gonorrhea, are as follows: (1) The law of gravity, acting upon the circulation when patient is in a standing position, increases congestion in the pelvic organs. Remedy: Absolute rest in bed in the reclining position, or better still, a modified Trendelenburg. (2) Exposure to sudden variations in temperature tends to increase congestion, especially of mucous membranes. Remedy: Maintenance of equal temperature in rooms occupied by patient. (3) Constipation, through direct pressure of compact feces upon the prostate, seminal vesicles, and upon the pelvic veins of other organs, retards circulation and causes congestion. Remedy: Maintenance of activity of the bowels, one or two semi-solid movements a day being necessary. This is accomplished (a) through eating regularly and in amount proportionate to the physiological inactivity engendered by rest in bed; (b) through choice of foods, as follows:

Fish:	All kinds boiled.
Farinaceous:	Brown, graham, oatmeal, whole wheat bread.
Vegetables:	Most kinds well boiled, as spinach, onions, brussels sprouts, cauliflower.
Desserts:	No sweets or pastries; figs, prunes, apples, baked apples, blackberries, cherries, plums.
Fruits:	Best taken before meals and between meals.
Beverages:	Plenty of water, at least eight to ten glasses daily; stimulants, none.
Forbidden:	Rich gravies, strong condiments, fried foods, hard boiled eggs, bananas, new bread, sweet pastries, alcoholic stimulants, rhubarb, tomatoes and asparagus.

*Read before the King County Medical Society, Seattle, October 19, 1914.

(c) through drugs, as magnesium sulphate, 1 or 2 drams night and morning, or other salines whose physiological action also helps to relieve congestion, aided by enemas when necessary. (4) Motion of inflamed area, either active or passive, causes con-

Fig. 1.—*a*, Mucous membrane, normal. *b*, mucous membrane, infiltrated. (After Motz.)

gestion. Active motion consists of (a) tenesmus through sudden constriction of the already overdistended blood vessels and pressure of the inflamed and swollen mucous membranes against one another; (b) erections. Erections increase congestion, and cause traumatism by stretching the swollen and inflamed folds of the mucous membrane of the urethra, which have lost their elasticity, (Fig. 1), therefore crack, thus producing fissures which permit the gonococcus to penetrate into deeper tissues. Remedy: Rest, secured (a) by preventing tenesmus through various means used to render the urine bland and mild (see chemical irritation, below); (b) by preventing erections through (1) inhibiting the use of alcoholic stimulants, especially beer, which cause erections through irritation of the urethral mucous membranes which reflexly excites the sexual centers, and through direct stimulation of the centers themselves; (2) prevention of overheating of the body, which causes reflex stimulation of the sexual centers and may be prevented by the use of a hard mattress, light bed coverings and by tying a towel around the waist knotted in the back so as to prevent sleeping on same; (3) through sleeping alone, to prevent excessive heat and sexual excitement; (4) avoiding sexual intercourse, even kissing, loving, and all scenes, exhibitions, literature, conversation, and company that will cause sexual excitement; (5) voiding the urine during the night at intervals of four hours, or more frequently if necessary, in order that pressure from an overdistended bladder may not cause erection; (6) if above treatment does not prevent erections, relieve same by gently massaging the seminal vesicles when the bladder is well distended, urinating immediately afterwards. By thus emptying these vessels, the reflex stimulation of the sexual centers due to the overdistention caused by lack of sexual intercourse will be relieved. Especially is this indicated in patients accustomed to regular sexual intercourse. Passive motion: Stripping of the penis by patient. This act is caused by patient's nervousness and anxiety to see rate of progress. It brings the inflamed and swollen membranes together, causing abrasions of the mucous membrane and the attendant evils. Remedy: Absolute prohibition of the act, instruction of the patient as to its harmful effect, and relief of discharge through local treatment to be spoken of later.

Chemical Irritation. The causes of chemical irritation are general and local. The general causes are: (1) Toxins produced (a) by constipation and other abnormal gastrointestinal conditions, which reduce the resisting power of the host and throw added work upon the kidneys and urinary tract. Remedy: Relief of gastrointestinal condition, especially constipation, as directed under Mechanical irritation (3). (2) Low vitality of the patient, due to various causes, as anemia, etc. Remedy: Relief of anemia, increasing the general circulatory activity, etc. (3) Improper diet causes by-products, irritating salts, etc., in the urine which irritate the inflamed mucous membranes. Remedies: (1) Hygienic: Care in diet, which preferably should be fluid for the first week, or light in character; tea and coffee may be used once daily, also lemonade, but all effervescent waters containing an excess of minerals, also alcoholic stimulants, are absolutely forbidden. (See also Mechanical irritation, 3); (2) Therapeutic: Internal medication, preferably sandalwood oil. So as to prevent any irritation of the gastrointestinal tract, this oil should be pure East Indian made freshly into capsules (5 grains or 0.30 gram), which should be as clear as water. These should be taken two every two hours for eight doses to cause saturation, then one every four hours or four in twenty-four hours. This drug renders the urine bland and mild and excludes irritation and congestion caused by acid urine, as well as obtaining rest by preventing tenesmus, frequency of urination, etc. Substitutes: Fluid extract of zea, two teaspoonfuls every two hours, or sodium bicarbonate, a teaspoonful every four hours. Local causes of chemical irritation will be treated under bacterial irritation, the two being so closely allied as to be inseparable.

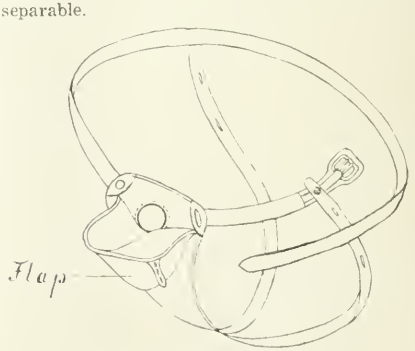

Fig. 2.—Teufel's suspensory.

Bacterial Irritation.—This is both mechanical and chemical. Mechanical bacterial irritation is caused by the activity of the invading organism and the results of their presence, as pus, increased mucous discharge, etc.; chemical bacteria irritation is

caused by toxins and other by-products which are the result of the activity of the organisms and the destruction of the epithelial cells, leucocytes, etc. Both causes retard circulation and increase congestion. Referring to the essential facts enumerated

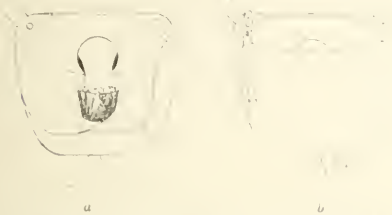

Fig. 3.—Suspensory in place: *a*, with dressing, cotton and rubber dam, on organ; *b*, flap closed holding dressing in place.

under the general headings "Gonococcus" and "Urethra," we note, since the urethra is lined with epithelial cells and the temperature of the human body is that essential to the reproduction of the gonococcus, that this tract is the best incubation tube for this germ known to medicine. It is but a natural conclusion, therefore, that whatever method will render the urethra a less efficient incubation tube will at the same time lessen the bacterial irritation and hasten cure. *Since the gonococcus duplicates itself every ten minutes*, it naturally follows that this rate of increase can only be compensated for, if we aim to destroy the gonococci, by the frequency with which we cleanse the urethra. This fact also shows the absolute fallacy of all methods of treatment which advocate the cleansing or medicating of the urethra three or four times daily and then permitting the patient to rest eight or nine hours at night without cleansing the canal of the discharge. Such prolonged period of freedom from treatment permits a greater increase in the number of gonococci through their reduplication during the night than can possibly be compensated for by their destruction through three or four treatments administered during the waking hours.

Remedy for Bacterial Irritation.—This is purely local in character, and can be placed under four headings: (1) Sitz baths. (2) Local application of heat. (3) Drainage. (4) Cleansing of urethra. (1) Sitz baths, two or three times daily; temperature 106° F. (41° C.) to 120° F. (50° C.); duration, three to ten minutes. The best method is to begin with a temperature of 100° F. (38° C.) and rapidly increase the temperature of the water until the maximum is reached. Protection from cerebral anemia should be given by means of cold compresses about the head or neck. The slightest chilling following the bath should be avoided (See Mechanical Irritation, 2), else the efficiency of the treatment is nullified. This may be prevented by giving the bath in a room of temperature equal to that of the bedroom, drying the patient with a coarse towel, and providing warm slippers and bath robe to be donned immediately. The bed should be warmed with hot water bottles before patient returns to same. (2) The patient should soak the whole penis in water as hot as can be borne every two hours, using for this purpose a bottle or bowl. Where foreskin is present, same should be retracted and thoroughly cleansed. (3) Drainage of the urethra. Poor drainage causes congestion and reinfection. Remedy: (a) If patient is circumcised, the meatus and part of the head should be constantly protected with a moist dressing of saturated solution of boracic acid, which should be held in place by a suspensory made as indicated in Figs. 2 and 3. Care should be taken that the suspensory does not cause constriction by fitting too tightly at the opening through which penis is inserted. As a substitute for the suspensory a bandage may be lightly applied and held in place by an elastic band, but not so tightly as to retard circulation. In either case, dressings should be changed according to the amount of discharge—at least every two hours or more frequently during the early stages. This dressing serves three purposes: First, it aids the escape of the discharge by preventing agglutination of the meatus by the mucus, which, because of gravity, collects, and being exposed to the air, dries, and so seals the discharge in the urethra; second, the antiseptic used destroys the activity of the gonococci in the discharge on the cotton and prevents reinoculation; third, it prevents infection from extraneous microorganisms which would otherwise collect about and enter the meatus if it were not protected. As mixed infection is one of the principal causes of the prolongation of an attack of gonorrhea, this dressing is one of the simplest means of hastening cure. (b) If the meatus is exceptionally small, the same should be opened, but not to such an extent as to vitiate its physiological function (See Urethra, e). (4) Cleansing of the anterior urethra. Remember the gonococcus lives at a temperature of 98.6° F. (37° C.) and is incapacitated or dies at a greater temperature, so the patient should use boracic acid solution or plain water, as hot as can be borne (to 120° F. (50° C.) if possible), every two hours dur-

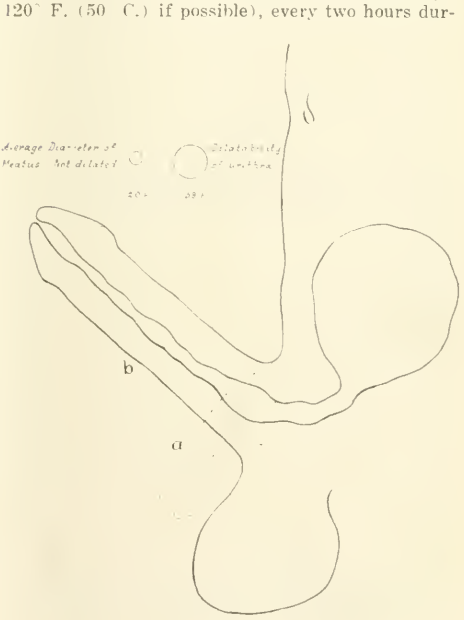

Fig. 4.

ing the day after soaking penis, and every three or four hours during night, patient having orderly or nurse awaken him, or should be awakened by an alarm clock.

Technique of Cleansing Urethra.—The urethra is

a collapsible canal, shaped irregularly (Fif. 4). When at rest the mucous membrane lies in folds (Fig. 5), which affords hiding places for millions of microorganisms. Correct medication of the urethra necessitates the cleansing of the entire mucous mem-

Fig. 5.—(After Motz.)

brane, which can be done only by distending the canal to its full capacity so as to obliterate every fold. The average capacity of the urethra is 15 c.c. (½ ounce); therefore a syringe of 30 c.c. (1 ounce) capacity should be used if all the folds are to be obliterated. Acute inflammation of the urethra causes swelling of the mucous membrane and loss of elasticity (See Essential facts, c) (Fig. 1); so sudden or forcible distention of the same would cause laceration, permitting deeper infection. Therefore, a bulb syringe (Fig. 6, a), the force of which can be regulated by the operator, should be used, not a piston syringe (Fig. 6, b). The care of this syringe is the same as that advocated for glass nozzles (See technique of irrigation, which follows).

A knowledge of the biological characteristics of the gonococcus teaches us that it invades the mucous membrane by penetrating between the epithelial cells. The epithelial cells of the urethra extend from the meatus to the bladder (See Urethra, d). Taking into consideration the infinitesimal size of the gonococcus (See Gonococcus, b) and its characteristic of penetrating between the epithelial cells, it is impossible for the compressor urethræ muscle (Fig. 7, 1) to contract sufficiently to prevent the onward march of the microorganism into the posterior urethra without crushing the epithelial cells, which it does not do. For this reason and the probable invasion of the gonococcus into the posterior urethra, hydrostatic irrigation which permits the irrigating fluid to enter the bladder and thus cleanse the posterior urethra, should be substituted, when the infection extends beyond the sphincter. The patient should irrigate himself, but not until detailed instructions have been given by a physician and proficiency attained through the physician's demonstrating the correct method of irrigation and the psychological character of the act—otherwise traumatism may be caused, which would defeat in part the purpose of irrigation.

Method of Irrigation.—The fluid will enter the bladder if the patient will remember the psychology of the act: *That he can urinate when he desires and that he can retain the urine as long as he wishes.* This demonstrates the fact that the compressor urethræ muscle (Fig. 7, 1) which controls urination is under the control of the will. Therefore, if patient wishes the fluid to enter the bladder, he must relax this muscle, which can be accomplished by thinking he is going to urinate and thus assuming the mental attitude that causes total relaxation of all muscles. In irrigation, no great hydrostatic force should be used, as force suddenly distending the urethra and impinging against this muscle will cause it to contract involuntarily and the resulting spasm will prevent relaxation. Naturally, full control of this muscle is not immediately secured. The desired control, however, is often easily attained by irrigating only the anterior urethra a number of times before attempting irrigation of the posterior.

Technique of Irrigation.—Apparatus needed: Two quart douche bag, glass nozzles, towel, basin. To prevent complications arising from infection from pyogenic microbes and reinfection by the gonococcus, etc., the glass nozzles should be made sterile by washing out with scalding water and keeping same in a 1:500 bichloride solution. Care should be taken that the nozzles are thoroughly free from the bichloride by washing with hot water before using, so avoiding chemical irritation that would aid rather than resist the bacteria in their attack upon the mucous membrane. The douche bag should also be kept clean by washing out with scalding water after each irrigation. The patient should be given the following instructions: Hang up douche bag so that force will be given to the water; loosen clothes and expose genitals. Pass all the urine from the bladder. Then sit on the edge of chair, bathtub, or

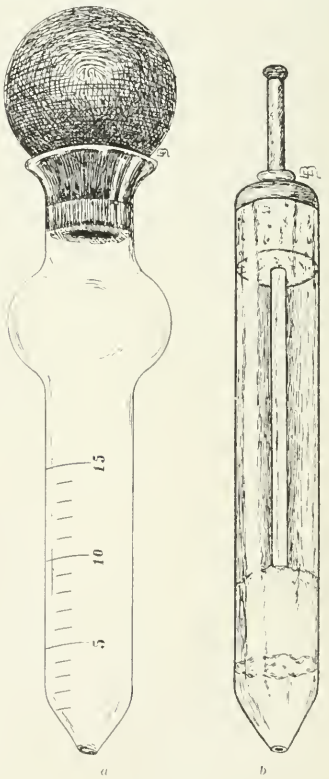

Fig. 6.

toilet, or if preferred patient may stand. If sitting, place towel beneath penis and over testes, placing basin on same beneath penis so as to catch irrigating fluid. Uncock clasp which shuts off water, and control fluid by clasping tube just behind the glass

nozzle with the index finger and thumb of right hand. The same thumb and forefinger are used to control the rate and force of flow. See that there is no air in the glass nozzle. Prevented by permitting plenty of fluid to flow from the tube into the basin,

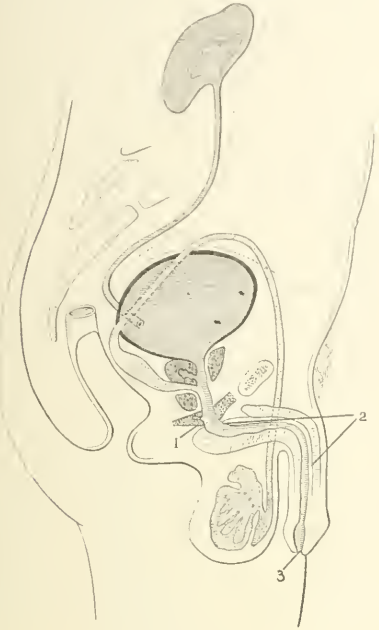

Fig. 7.

the nozzle being held upright so as to permit air to escape. Grasp the head of the penis with the left hand and apply the nozzle to the mouth of the urethra. First wash out the front part well. This is done by holding the nozzle loosely at the meatus. After this is done, allow the fluid to gradually distend the anterior urethra, then release the sphincter so as to permit the medication to enter the bladder. When bladder becomes filled, immediately void fluid so as to reirrigate the canal. Injections, when warm water or boracic acid is used, should be repeated at each irrigation until the fluid returns clear.

Local Medication.—The object of all local antigonorrheic medication is to kill the gonococcus, but antiseptic drugs sufficiently strong to kill bacteria are also very apt to destroy the vitality of the tissues with which they come in contact, and in so doing they would here retard rather than aid the host in overcoming infection. Therefore, as frequent irrigation, because of the rate of reduplication of the germ, is the chief factor in destroying the gonococcus, strong antiseptics are contraindicated, because frequent use, even of weak solutions, irritate the mucous membrane. To date mankind possesses no drug that is bacteriotropic for the gonococcus and nonorganotropic for the epithelial cells. So, until all acute swelling (edema) of the mucous membrane has subsided, there should be no local medication except boracic acid solution or hot water. Later, possibly some albuminous silver salt, because it is nonirritating in fairly strong solutions, may be employed, such as argyrol, 20 per cent., or protargol, 1 per cent., to be used in the following manner.

Technique of Medication.—Apparatus needed: Hot water, bulb syringe, one rubber glove for left hand, two towels, two basins, one empty, the other containing 1:500 bichloride solution and cotton sponges. Place rubber glove on left hand. This is for the purpose of preventing silver stains. Patient should first void urine, then cleanse anterior urethra by means of syringe with water as hot as can be borne. This is absolutely essential in order that the medication may not only come in direct contact with all the inflamed membrane, but penetrate between the tissues. Patient should sit on chair in manner described under irrigation. Holding head of penis lightly with thumb and forefinger of left hand, inject the silver salt into the canal with bulb syringe very gently, but to such an amount as will thoroughly distend urethra. Then grasp penis at head tightly with thumb and index finger, retaining the solution for ten to fifteen minutes. It is to be remembered that part of the efficiency of the albuminated silver salts depends upon its penetrative power, which is in proportion to the amount of pressure under which it is retained. Therefore, as above stated, the patient should distend the urethra thoroughly, but not to the extent of causing pain. While patient retains solution, the empty basin should be placed beneath the organ so as to catch any escaping fluid. At the end of ten or fifteen minutes patient should allow the fluid to escape into this basin, then immediately take the basm of bichloride solution and wash off with the sponges all the excess of stains on hands and organ. Then apply cotton placed in rubber tissue (Fig. 8) over head of penis, thus not only retaining the remaining silver salt solution, but also preventing staining underwear by the escape of same. Frequency: These injections may be substituted once or twice daily in place of the irrigation by hot water, if they do not cause too much irritation. At the end of a week, if there is little pus and much mucus discharge, permanganate 1:6000 or 1:2000, or a solution of silver nitrate, 1:10,000 or 1:3000, may be used.

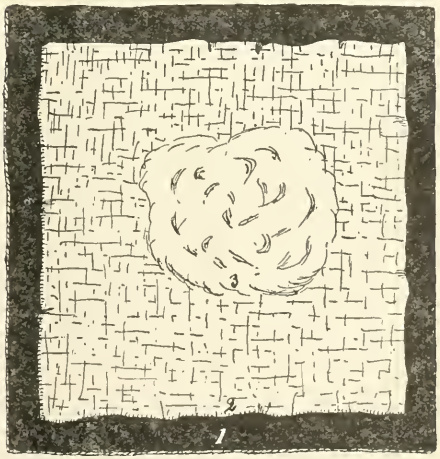

Fig. 8.—1, Dental dam; 2, lint; 3, cotton.

Directions as to how the solution should be used, though not irrelevant here, constitute so large a subject that they must be omitted. Even if presented they would only aid in attaining proficiency.

for proficiency comes through experience, based on observation, experimentation, and reasoning. The first step in obtaining experience in inflammatory diseases of the urethra is the formation of a definite premise upon which to base one's deductions. The definite premise here is the daily observation, macroscopically and microscopically, of the urine *held for a definite length of time* (*four hours*) in a number of normal individuals under varying hygienic conditions. Using this knowledge as a basis of comparison, daily examination of the urine held for four hours in cases of specific infection, will enable one to ascertain with certainty the progress of the disease, the efficiency of treatment and whether instructions given are carried out correctly. Treatment based on such logical experience will produce the greatest percentage of results, since it is rational and varies with the individual, and is not empirical.

Summed up, (1) absolute rest in bed, (2) building up bodily resistance, (3) relieving congestion and increasing circulatory activity in the area affected, and, (4) frequent cleansing of the urethra according to scientific knowledge will cure most cases of acute gonorrhea in two weeks and leave the minimum per cent. of pathological after effects, if the

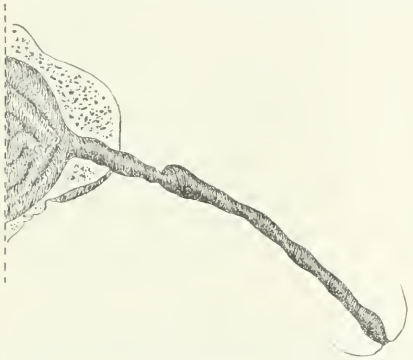

Fig. 9.—Cast of normal urethra. (After Deaver.)

treatment is pursued systematically and with care in detail as here described.

Treatment will be pursued systematically and with care as to detail best in a hospital, but even then only when patient and nurse, as well as physician, thoroughly understand why each order is given and how each should be fulfilled. Then will intelligent cooperation be secured and results attained, due to the fact that the individual, and not a disease, is being treated. If the patient thoroughly understands the correct method of obtaining the object to be desired and does not follow instructions, the responsibility is his and the attendant inconveniences—prolongation of the attack, added cost, etc.—must be borne by him without complaint. If, on the other hand, the physician fails to give intelligent and explicit instructions to the patient and nurse, the responsibility rests upon the physician's shoulders. In any event, if explicit instructions are not given, responsibility for lack of results is placed upon the individual, where it belongs, and not upon the science of medicine.

I realize that the first criticism of the treatment here advocated will be: The difficulty of securing acceptance by the patient because the initial cost in time and money appears so great. True; but nature's laws are immutable and man's success is in proportion to the correct interpretation of the workings of natural laws, and if the mandates of the physiological and pathological laws (varying not only with the host but the invading organism) which eradicate gonorrhea are not carried out absolutely by both physician and patient, maximum results will not be attained, for the mandates of these laws give no option, either to physician or patient. This treatment is the correct treatment, inasmuch as it is based upon the natural laws governing the disease, in so far as we have been able to interpret them correctly to date. If this treatment is the correct treatment, all other treatments are at best substitute treatments. However, the technique of ambulatory or substitute treatment of gonorrhea must be reserved for another article.

1. THE GONOCOCCUS.

(a) The gonococcus is a microorganism. Its power to resist destruction varies with its environment, not only with the different organism of the same species, but also with the same organism at different times. (b) Its measurements are 0.0016 mm (.000064 in.) in length and 0.0008 mm (.000032 in.) in width. It is so small that to appear the size of the head of a pin it must be magnified twelve hundred times. (c) To be seen it has not only to be magnified, but stained. To be classified, it has not only to be specially stained (Grams stained) but sometimes cultivated, and even then its identity may be questioned. It lives at a body temperature of 98.6° F. (37° C.). Its natural environments are the epithelial cells of the body, especially the columnar cells of the anterior urethra. This microorganism penetrates between the cells to the subepithelial connective tissue, which it does not penetrate unless the vitality thereof is impaired, as by trauma, etc. (d) *It duplicates itself every ten minutes.* (e) It produces while living antibodies which can be found in the blood by means of a complement fixation test or blood test.

2. THE URETHRA.

(a) In a collapsed condition, the urethra averages six inches (15 cm.) in length, the size varying with the individual and the size of the penis. During erection a urethra six inches (15 cm.) long will stretch to a length of eight (20 cm.) or eight and one-half inches (21 cm.) and expand proportionately (Fig. 4, a and b). This signifies that upon collapsing, the lining or mucous membrane must be thrown into folds, which are in contact with each other, as illustrated in the magnified specimen (Fig. 5), a cross section of the male urethra collapsed. (b) Anatomically, it is divided into three parts, the pendulous portion, the membranous and the prostatic. Mechanically (*i.e.* for practical purposes) it is divided into the anterior and posterior urethra, this division being due to the compressor urethræ muscle (Fig. 7, 1) or shut-off muscle, which is under the control of the mind and permits man to void or retain the urine at will. It surrounds the urethra so tightly at the membranous portion (Fig. 7, 2) that no fluid can pass out of or into the bladder until it relaxes, therefore its employment as a line of division. That portion of the urethra anterior to the muscle is called the anterior urethra; and all posterior, the posterior urethra. (c) The diameter of the urethra varies, the narrowest portion being the meatus (Fig. 7, 3), the next narrowest commencing at the membranous urethra, the variation in size and configuration being well illustrated in Fig. 9, a cast of a normal urethra. (d) The urethra is a mucous membrane. It is formed principally of epithelial cells, the anterior of simple columnar cells, the membranous of stratified columnar and the prostatic of transitional epithelium, but each kind gradually merges one into the other. (e) The meatus (Fig. 7, 3) is a nozzle to give resistance to the semen and stream of urine, so that both will be projected, and in the case of the urine so that it will distend the folds of the urethra and keep same clean and maintain the tonicity of the mucous membrane, thereby its power of resistance to disease.

3. THE HOST OR INDIVIDUAL.

Recognizing that immunity and susceptibility to microbic infection vary with the different individual

or host and with the same host at different times, and that this fact must be taken into consideration, we come to the main subject of investigating the pathological condition in the urethra—an inflammation. (a) The causes of inflammation are (1) bacterial, (2) traumatic, (3) chemical, (4) nervous. Primarily, the cause of gonorrheal urethritis, uncomplicated, is the gonococcus of Neisser. Causes superadded and to be prevented as producing complications are other bacteria (pyogenic organisms), traumatism, chemical, etc. (b) Attacked by bacteria, the host resists and attempts the destruction of the invading organisms, with the result that the phenomena of heat, pain, redness, and swelling of the mucous membrane occur. (c) The means of resistance employed by the host to destroy bacteria are chemotaxis, phagocytosis, and the use of the lysins of the serum. (d) The efficiency of chemotaxis, phagocytosis, and the lysins depends mainly upon the reduction of congestion and the increased circulatory activity of the area attacked.

4. THE VARIOUS THERAPEUTIC AGENTS.

These consist of such means as will aid the host, attain the result aimed at—the destruction of gonococci—by chemotaxis, phagocytosis, and the use of the lysins through assisting and not interfering with the working out of the physiological and pathological laws which eradicate disease.

VACCINES IN RELATION TO MOUTH INFECTION.

By JOSEPH HEAD, M.D., D.D.S.,

PHILADELPHIA.

As in the treatment of all diseases with vaccines the depots of infection must be removed by every means possible so that the work of the antibodies will be reduced to a minimum. This is particularly the case in the treatment of mouth infections, and all of the bacterial masses, dead epithelial scales, and food remnants must be carefully removed each day with floss silk, tooth brush, and mild washes if the vaccine treatment is to prove of value.

When the bacterial masses have been removed so that only a thin film remains, there are two mouth washes that may prove exceedingly valuable as a means of discouraging further growth until the time arrives for the next cleansing. These two washes are one per cent. peroxide of hydrogen made slightly alkaline, and a saturated aqueous solution of sodium silicofluoride which has a strength of 0.61 per cent. These washes held in the mouth for a minute or two after the mechanical cleansing prove of value clinically, and their daily use is of great assistance in reducing the areas of mouth inflammation. This is particularly interesting as Anderson has shown that peroxide in such strength for such a time has no carbolic acid coefficient, and researches by Hitchens has proved the same thing about sodium silicofluoride as a mouth wash. And yet they are of value clinically. Ehrlich in his address appearing in the *Lancet*, Aug. 16, 1913, showed how the *Spirochæta pallida*, when subjected to the action of salvarsan had the same mobility and life apparently as the organism that had not been so treated; and yet the *Spirochæta pallida* treated with salvarsan could be digested by the leucocytes in a manner impossible when the organism had not been subjected to the action of salvarsan. May not this be the explanation of why non-antiseptic mouth washes are at times more effective than those that have a high germicidal efficiency? May not the mild peroxide or sodium silicofluoride sensitize the germs so that the ferments of the blood or saliva can digest the otherwise undigestible germs? This is advanced as a possible explanation of the unquestioned value of certain washes that of themselves seem inert.

In addition to the regular daily hygiene of the mouth it is necessary that all dead or infected pulps should be carefully removed and the root canals filled, for many pockets of infection around teeth with living pulps resist all systemic treatment or local applications until such depots of infection have been removed. It is also just as essential that all tartar should be carefully curetted from the roots of the teeth, as its presence always acts as a source of infecting irritation. There is also another valuable therapeutic agent for softening tartar scale and reducing the inflammation of the gums in the weekly applications of the acid hydrogen ammonium fluoride. This consists of 20 parts hydrogen ammonium fluoride, 10 parts free hydrofluoric acid, water q.s. to make 100. This, according to the tests of Hitchens, has a carbolic acid coefficient of 5.82, and should be applied with a platinum pointed syringe with a celluloid barrel as it attacks glass. This drug, when properly used, with careful instrumentation is particularly effective in the local treatment of mouth infection. For unless the tartar scale is absolutely removed, healing and reattachment of the infected gums to the roots is impossible.

When we come to the systemic treatment of mouth infection a judiciously selected vaccine, in my opinion, gives most excellent results; but since the local and general treatment should always be used in conjunction, it is often difficult to determine the exact proportion of credit for the cure that should be given to each. The local treatment alone has been so effective at times that I am forced to admit that had I been using the vaccine the vaccine would have had a measure of credit. And yet I am convinced and am morally sure that as a general condition, properly selected vaccines cause a healing and a permanency of result that are impossible with local treatment alone. In fact, the results of vaccine treatment are usually cumulative, as shown by the continued improvement in the local conditions for a year after the course of vaccine treatment is finished.

And so the four principal drugs I have used in the treatment of mouth infection are: Hydrogen peroxide, sodium silicofluoride, acid hydrogen ammonium fluoride, and vaccines. All drugs have disadvantages as well as advantages. The advantages of these drugs have been dwelt upon, their disadvantages are as follows: One per cent. peroxide cannot be used in some mouths without causing great irritation. Sodium silicofluoride wash is generally useful in reducing inflammation and tartar scale, but in about one per cent. of the cases increases the deposit on the teeth or causes nausea; ordinarily, it is considered agreeable as well as useful. The bifluoride properly applied is invaluable, but is exceedingly sour and disagreeable. It also causes nausea to a small percentage of patients. However, the great proof of its efficiency lies in the fact that patients generally submit to its weekly applications for long periods of time. The vaccines have the great disadvantage of occasionally causing headaches, nausea and various reactions in the muscles and lymphatics. In rare instances there is the appearance of a rash, and mild symptoms of serum sickness. This latter, with vaccine is almost negligible since 3 billion staphylococci or streptococci weigh only a milligram or less.* Thus, if these microorganisms were considered as pure protein,

*Wilson & Dickson: *Journal of Hygiene*, Vol. XII, Page 49.

which they are not by a large per cent., these appalling doses of bacteria would contain less than a fourth of the protein found in 0.05 c.c. of horse serum. And 0.05 c.c. of horse serum is the dose suggested by Vaughan as a preliminary dose to be given to a patient as a test, whether he can safely take antitoxin.* According to Lewinsky, horse serum contains 80.4 mg. of protein per cc.

In forty-two of my cases, the complete bacteriology of which has been reported by Dr. Claude P. Brown, the presence of six principal germs was noted in such a large proportion of cases that the scattering of other germs appeared so insignificant as to make them seem almost in the light of accidental flora.

These germs were: Streptococcus, among which, especially in winter, was found the *Streptococcus viridans;* pneumococcus; *Bacillus influenzæ; Micrococcus catarrhalis;* diphtheroids, and staphylococci. It was decided to take all the strains of these germs occurring in these forty-two cases, and after mixing them, form a stock vaccine, of which each cubic centimeter of syringe A would contain pneumococcus, streptococcus mixed, *Micrococcus catarrhalis,* 12½ million each; *Staphylococcus albus* and *S. aureus,* 50 million each; *Bacillus influenzæ* and diphtheroids 50 million each. Syringe B contains twice as much as syringe A; syringe C twice that of syringe B, and syringe D twice that of syringe C. So that syringe D contains pneumococcus, streptococcus, *Micrococcus catarrhalis,* 100 million each; *Staphylococcus aureus* and *S. albus,* 400 million each; diphtheroids and *Bacillus influenzæ,* 200 million each. This vaccine has given most encouraging results, and a few of the cases in which it was used will be specifically reported, but I hope in another year to be able to make a more complete report that will throw conclusive light on its therapeutic value.

As the consistency with which these seven germs were found in the pockets of infection around the teeth may be due to the method used in taking the material for the vaccine, a description of my technique may prove of value. The tooth should be protected from mouth contamination by a sterile napkin. The neck of the tooth adjacent to the pocket of infection should be then thoroughly washed with cotton soaked in salt solution and then dried. This will remove the masses of extraneous mouth flora. The edges of the pocket of infection and the adjacent tooth should now be slightly seared with a cherry red cautery which can be accomplished with practically no pain to the patient, and then a small cup-shaped spear of thin platinum should be heated to a cherry red and plunged to the bottom of the pocket. In this way a two-fold purpose is at once accomplished. The extraneous germs near the edge within the pocket are destroyed and the deep seated germs alone are collected on the thin platinum point which has cooled before reaching them. This renders it possible to carry to the blood agar only the germs directly responsible for the disease in question. The vaccines so obtained were made up to contain all the germs found except the spore formers and the anærobes. While it is possible that the bacteria of these classes may play a rôle in the infections, my experience indicates that this rôle is a minor one.

Of the seventy cases reported I shall first classify them according to the reactions of the vaccine. Of those cases that received the standard dose up to the full amount per cubic centimeter, without local or systemic reaction, there were thirty-nine. Of these thirty-nine cases, eight received a second series of treatments at more than six months intervals from the finish of the first series, and one of those eight even a third series of treatments. Of these eight cases, four received the second series of vaccine with equal complacency, while the other four showed decided reaction systemically and locally. Whether this was due to a change in the character of the vaccine or whether it was an allergic reaction, is a question. Of the seventy cases, fourteen were conventional in their reactions and required only normal care. Of the others, fifteen required the utmost care and attention, and the fact that a dose was well received without a reaction one time was absolutely no guarantee that it would be received with any tolerance the next time. In fact, these fifteen cases demanded the utmost watchfulness in the vaccine treatment, and it is such cases as these that make it necessary that vaccines should always be associated with the greatest care in general diagnosis, and the utmost circumspection during administration. The extraordinarily good results as shown by a local healing of the mouth was noted in twenty-one cases associated with nine instances of no local or general reaction, six of normal reaction, and six of severe systemic response. Of the cases showing marked systemic improvement there were altogether ten. Of these, six showed no systemic reaction, two were normal, and four were of the severe reaction type. I shall not go further into this tabulation, as to do it efficiently a greater number of cases are required. The table, however, is fairly instructive and may throw further light for those who care to study it.

In reference to the dosage where there was no special reaction a quarter of a cubic centimeter was given the first time, a half the second week, three quarters the third week, and finally the full cubic centimeter the fourth week, which was continued week after week unless a reaction occurred. A reference to the table will thus make it possible to see just what doses were used in these cases where the reaction is marked O. All the strains of the various bacteria were put in 50 million each except those of staphylococcus that were put in 300 million per cubic centimeter up to Patient No. 45 of the table. But later each species was put in only once, all the various strains being mixed in one counting so that after Patient No. 45 of the table, the combined strains of each species would be inserted in the vaccine to the number of 50 million each, except in the case of the staphylococci, which were combined to the number of 300 million per cubic centimeter. This deduction was made in order that a more delicate graduation of the dose might be possible. This statement makes it possible for those interested to figure out the average bacterin dosage per patient.

When the blood count showed excessive lymphocytosis before treatment the first dose was 1/10 of a cubic centimeter. Lymphocytosis appears to be the rule during the administration of vaccine. The dosage associated with the usual reaction (in the table) is marked 1. Unusual or extreme reaction is marked 1+. The reaction or absence of reaction appears to be associated with the tolerance of the patient to the vaccine more than whether the dose is large or small in amount, and an intolerance may suddenly develop to a dose that has been well borne many times previously. For instance, in Case No. 24 there were positively no symptoms of reaction dur-

*"Protein Split Products," page 471.

ing the whole treatment. The patient, a strong man of 50, stood a very large dose containing *B. influenzæ*, a Gram negative bacillus, four streptococci, a pneumococcus, and a tetragenus in amounts of 50 million for each germ, making for Case No. 24 100 million B. *influenzæ*, 200 million combined streptococci, 50 million pneumococci, 50 million tetragenus, and 300 million staphylococci. There were practically the same doses and results for Case No. 25, a young married woman of 37. On the contrary, Case No. 16, a married woman of 40, 40 million streptococci could not be borne once a week, and the case required constant watching and dose modification, although in all three cases the results from a local and systemic point of view were equally satisfactory. As has been before stated, dosage depends upon the individual to a marked degree, some accepting easily what would cause great disturbance in others. Probably the acuteness of the inflammation and the number of the depots of infection are responsible for these so-called idiosyncrasies, and these facts still further emphasize the necessity for thorough physical examination and diagnosis before the vaccine treatment is commenced.

In reference to intolerance being developed by a dose previously well borne, I shall quote the action of a series of doses of the stock pyorrhea vaccine as shown on myself and marked in the table as No. 44. My bacterial mouth infection analysis shows the presence of 2 streptococci, a *Staphylococcus aureus*, 1 *B. influenzæ*, 3 *M. catarrhalis*, and a diphtheroid. My teeth were very loose and painful, and the local treatment was only partly successful. Therefore, because my analysis was so near the stock vaccine in structure and I was anxious to try its effect personally, I did not use an autogenous vaccine, but started last July to take the stock vaccine, and have taken forty-six doses at weekly intervals. As stated before, syringe A contains: pneumococcus, streptococcus, a Gram negative coccus, each 12½ million; *Staphylococcus aurcus* and *albus*, each 50 million; diphtheroids, and *B. influenzæ*, each 25 million. Syringe B = twice that of A; syringe C = twice that of B; syringe D = twice that of C. I took A, B, C, D in the first four weeks and then continued with D until 28 doses had been taken in weekly intervals. All this without any reaction or discomfort worth mentioning. The 29th dose caused my arm to be sore for 24 hours, with a slight soreness in the axilla, and a continuance of the induration that made me feel the digestion was not so perfect as heretofore. I then used syringe C for eight doses without reaction, and the ninth dose caused nausea and depression for 24 hours. The next week I used syringe B and had a slight depression; the next week B gave no depression, but the induration persisted, so I used syringe A. The next week I returned to B and got a distinct reaction, and so returned to A for two weeks, and then found that A gave a reaction, and then used 6/10 of a cubic centimeter of A, and last ½ A, and then stopped, not being able to bear with comfort more than one-half of the first minimum dose. In the meantime, my teeth have tightened, my gums improved, I have almost entirely lost my former tendency to take cold, and I am in better health than I have enjoyed for years, which I attribute to the elimination of the toxins of the mouth infection from my system. Why I developed an intolerance for the vaccine I do not know.

Another patient, Case No. 2, is having the same experience. It is her third course of vaccine treatment and the stock vaccine was used. Syringe A was given without reaction. After the first dose of syringe B she had swelling of lips, itching on back. After syringe B was given three times, syringe C was given without reaction. D was given eight times without reaction and on the ninth nausea appeared. Syringe C was then given without reaction for ten times. Excessive soreness of the arm and sharp pains in the chest caused a reduction of the dose to B. This also caused a renewal of the reaction and the dose was reduced again to A, which she took five times at the usual weekly interval.

This patient, described as Case No. 2, is a widow, aged 35, who came to me three years ago so anemic and thin that she looked as though she were in the first stages of tuberculosis, although physical examination revealed nothing radically wrong. Her mouth was badly infected. Since the treatment her mouth has healed, her skin cleared, she has gained in weight, and all of her friends when noting her improved health are told by her that she attributes it to the vaccine. I have noticed this same series of phenomena in other cases to a less degree.

I have found the study of blood counts most interesting and valuable as a diagnostic and therapeutic guide, and perhaps a slight résumé of some of these might prove of interest.

Case No. 16. Married woman, 47, under treatment for two years. Gout in right eye, great depression with constant fatigue. Gums made more progress under a streptococcus vaccine in six months than she had previously made in two years. When she started, her hemoglobin was 67, and at the end of the first series of treatments rose to 93. The other vaccines were given as shown by the table, but the hemoglobin remained just the same, practically, and the white blood corpuscles, that at first had been 5,500 per c.mm., consistently rose to 7,200. Her teeth and gums are now almost completely well, but as she is still gouty and as she is at the menopause, there will probably be relapses from time to time that, however, can be readily controlled.

Case No. 64 was another illustration of an interesting blood count series. A man of 40 suffering from acute general mouth infection complicated with general physical depression. Hemoglobin 80, white blood corpuscles 16,000. Local treatment was instituted and an autogenous vaccine (streptococci and staphylococci) prepared and given. In two weeks his leucocytes had dropped to 12,600 and in nine weeks to 9,500, while his hemoglobin had risen to 90. In the meantime his gums had healed, his spirits improved, he gained in weight, and he is practically well.

There are many interesting changes in the blood count during the administration of vaccine in the treatment of mouth infection, and I feel that a comparison of data in this field may prove of great value not only scientifically but from the dosage point of view. For instance, Case No. 65, a man of 40 with pronounced pyorrhea, was given a vaccine of streptococci and diphtheroids, 50 million each per cubic centimeter. He had no reaction and took the full dose without any symptoms at all. So little was he affected that unknown to me, after his injection, he would go off and play squash. His hemoglobin at the start was 84, erythrocytes 4,860,000, leucocytes 9,400, polymorphonuclears 68 per

cent., combined lymphocytes 22 per cent. With continued improvement during six weeks, local and general good health, his hemoglobn dropped to 72, his leucocytes to 5,500, and the differential count showed polymorphonuclears 4.9, transitionals 54.9, and lymphocytes 33.3 per cent.

George Washington's maxim says, "you should not tell things in company that are hard to believe." I did not make the blood count myself. I give it as I received it. I, however, shut down the vaccine to 1/10 cubic centimeter and took another count in two weeks, when the hemoglobin had risen to 78, the leucocytes 6,500, the polymorphonuclear neutrophiles 4, transitionals only 12.5, while the lymphocytes combined had gone up to 44 per cent. Shortly after he went away with his gums completely healed and his health apparently perfect. His blood count in the fall will be of great interest.

Case 61. Married woman of 38 with great local and systemic improvement showed an increase of hemoglobin from 61 per cent. to 75 per cent. during a period of eight weeks. Her leucocytes had also dropped from 8,000 to 4,000, and as her erythrocytes had also dropped to 2,568,000, it was decided purely on her blood count to stop the vaccine until the fall, when another blood count could be made. Through a mistake the original red blood corpuscle count was not made, so just how much the red cells had really fallen off can only be surmised. When the treatment was commenced there was a lymphocytosis of 45 per cent; in four months this rose to 49 per cent., and in two months dropped to 40 per cent.

Case No. 59. A married woman of 35, mouth infection pronounced in three or four teeth, but not general. Hemoglobin at the beginning was 55 per cent.; in six months it rose to 75 per cent. At the beginning of treatment the red cells were 4,035,000; in six months they had dropped to 2,720,000. The leucocytes in six months also dropped from 7,500 to 3,100. There was practically no lymphocytosis at the beginning or end of the treatment. This was interesting, as my experience would indicate that vaccine treatment usually causes a lymphocytosis. On account of the falling off of the leucocytes and the red cells, the treatment was temporarily stopped, although the patient was gaining in weight and showing improvement in every way locally and generally. More interesting facts might be cited along the lines of the blood count, but it would seem advisable to wait for a greater supply of data. These figures, however, certainly tend to indicate that in the blood count we have a sensitive index of the patient's condition, and in the future the frequent taking of complete blood counts will figure largely in my routine treatment.

In summing up my paper I would say that local surgical treatment for the removal of infecting masses is the first essential. Non-germicidal washes such as hydrogen peroxide and sodium silicofluoride may sensitize the thin bacterial films so that the ferments of the mouth and tissues can readily control them. Vaccines properly selected and given are of unquestioned value. The blood count also may prove of great value as a guide to dosage.

Scarlet Fever in the Aged.—C. B. Ker records a case in a man, aged seventy-four years, complicated by otitis and arthritis. In a total of 263,986 cases treated in modern fever hospitals, Ker could find only twenty in persons above 60.—*Brit. Journ. of Children's Diseases.*

ARE WE GETTING PROPER VALUE FROM OUR PLANT AND EXPENDITURE FOR THE TUBERCULOUS?

By EDWARD S. McSWEENY, M.D.,

CASTLETON CORNERS, STATEN ISLAND, N. Y.

MEDICAL SUPERINTENDENT, SEA VIEW HOSPITAL.

My answer to the question is "No." Fortunately, now there is a chance to do something; a widespread demand for economy insures common sense a hearing, if not respect. Not only does there seem a chance to stop an abuse, but the opportunity is presented of doing something for the tuberculous who can be helped, for I hold it absolutely true that every cent spent foolishly or uselessly is a cent stolen from the rightful beneficiaries. Means, no matter how actually great, are always proportional to the demand, and there practically never is such a superabundance that the real work to be done does not suffer from waste.

To maintain that as high standards are possible as would be if the number of patients were materially reduced and the staffs of the institutions relieved of the distractions incidental to the presence of a large number of misfits, is to go contrary to all experience. Tuberculosis is not quite so peculiar a problem as to differ in this respect from everything else. The consumptive who can be and should be helped is suffering from bad management. I believe the management is so bad that if its faults were corrected, not only would there be ample means to take care of the proper tuberculosis cases properly, but there would actually be a balance over.

Here I may say that I am going to deal with only one phase of the matter—Institutional Care. The subject as a whole is too big to attack in a short paper, though much the same criticisms are applicable throughout.

Let us first consider what the present state of affairs is: An enormous number of tuberculous patients of all kinds and stages of disease and an annual expenditure on them of millions of dollars. Need, therefore, one would think, that care be used to insure each getting just what he or she required, and good reason for careful consideration of how the money is spent, so that every dollar expended will yield a dividend to the patient or community, or both; but this, strangely, does not seem to have materially influenced action, for, while tuberculosis institutions bear all sorts of names and allege all sorts of objects, practically all house a medical and social hodge podge that bears small, if any, relation to the professions of their conductors. Anyone who can be caught, no matter who or what he is, and can be proved to have a tuberculous or possibly tuberculous lesion, in he goes with the rest, without reference to the probable results. The highest type of case sets the standard, and the expenditure is the same for all.

So much for what we have and what I condemn. The more you know about tuberculosis institutions the less you will question my description. Ordinarily in assuming a position of sharp criticism of existing conditions and in offering reasons for dong so, as is proper when seriously differing on important points from the accepted state of affairs, one is put to some trouble in combating the solid arguments of opponents. But here we find the remarkable anomaly of every sound medical and social consideration being in opposition to the prevailing practice. The matter of treatment is fundamentally a

medical question, but we find that action at present is largely based, if it have any foundation at all, on a wholly erroneous impression of the nature and course of the disease. There is no excuse for medical men not realizing this; but that the public should not plainly see it, too, from the results, is astonishing. From the lack of accommodation for any others, moreover, it would seem that adult tuberculosis, other than pulmonary, was unknown.

If we stand on the firm ground of the pathological process and the clinical course of tuberculosis we can not only maintain that the social often outweighs the medical, or perhaps better expressed, the pathologic classification of the patient, but also that because a person has tuberculosis it by no means always constitutes an important factor in his condition, and can urge the following classification and program as the only one by which our plant and expenditure can be made to yield its full value:

1. Cases of criminality, insanity, epilepsy, feeble mind, old age, permanent disability of other origin, alcoholism, and vagrancy, complicated by tuberculosis, should not only not be treated in view of it alone, but the primary condition should be considered first and the tuberculosis regarded as a complication. This implies tuberculosis departments in institutions for these classes. It is done to some extent now in some of them, largely in criminality only and not at all in others. On the one hand, when we know that the tuberculosis has little or nothing to do with or only bears an indirect relation to the individual being a public charge, and there is often no profit for the patient or anyone in treating it, why not have the honesty to say so? On the other, the principle once adopted, especially regarding vagrancy, would largely solve the tuberculosis hospital problem for New York City. The time and effort spent in admitting, discharging, and readmitting these people first to one place and then to another are absolutely without effect, while consuming a large fraction of the available resources, because the whole proceeding is stupid from the beginning. If that were done at first that should be done, there would be but one admission, the patient would be placed where he or she belonged and could be kept, and the space and money so saved used for its rightful purpose. I hold no brief for the lazy, incorrigible, or ne'er-do-well. My efforts are not going to be devoted to coddling tramps and other parasites, but in obtaining their rights for the decent consumptives, which is wholly impossible under present conditions, and in adding my strength to obtaining for those who foot the bills good value for their money. If a tramp has tuberculosis, he should be treated for it, but because he has tuberculosis is a mighty poor reason for not dealing with him as a tramp. Why sacrifice your major classification for the minor and just because a man or woman has tubercle bacilli in his or her sputum or lungs, which is only one factor in their condition, and perhaps not a factor at all, take them away from the place designed for their kind and where they can perhaps be benefited, and put them in a place where they do not fit, do them the least possible good and spoil your other institution? This class is the crux of the whole problem.

2. Cases of chronic disability, due to pulmonary impairment of tuberculous origin, should be kept in tuberculosis homes with infirmary service, to be retained there until death. In a paper read some years ago I stated strongly my opinion, which I still hold, that despite the fact that for tuberculosis no cure in the ordinary sense of the term is known, it is the only disease of this class in which everyone is agreed as to the proper method of treatment, and that one of the greatest factors of success in the antituberculosis propaganda is the assistance of the tuberculous themselves, which can be procured only by preaching the doctrine of hope. Nevertheless, there is no need of making ourselves ridiculous, and when we have a case disabled beyond repair, even if the tuberculosis should be arrested, even if we think he will perhaps live for years or die of something else, what is the use in placing him in a tuberculosis sanatorium or hospital with cases that give a reasonable prospect of active, useful life? Nothing is perhaps so protean in the catalogue of disease, so hard to classify, not even common colds, but there are limits even in tuberculosis. There is no sense in the present plan, which, ignoring everything but the fact of demonstrable changes in the lungs of tuberculous origin, puts every case in the same institution, all getting the same treatment and the same care and the same expenditure, just as if the same result could be expected in all. Moreover, it is not only useless, but it is wrong and foolish to make these folks miserable by the discipline and routine of a tuberculosis hospital as regards exposure to the cold, restrictions of various kinds (*e. g.* alcohol and smoking), repeated medical examinations, supervision in detail, etc., etc. Disabling tuberculosis of a chronic type not only does not necessarily, but in practice almost never yields such improvement from treatment as to restore the individual's self-supporting capacity. To make such cases happy and hold them indefinitely without legal commitment in a tuberculosis home should be easy. To do so in a hospital has been proven impossible. The reason is obvious. In one case the patient's comfort and pleasure can dominate the situation; in the other, the medical aspect demands first consideration. To do the right thing would here cost a great deal less than doing the wrong thing does now.

3. Cases of chronic tuberculosis without disablement should not be treated at all. Whatever the stage anatomically is immaterial. Let us remember that tuberculosis, even to a considerable extent, is perfectly compatible with excellent general health under conditions of normal life and occupation, and such tuberculosis does not necessarily show any results from any known treatment. There are two conditions to be always differentiated—tuberculosis infection and tuberculosis disease or toxemia, or technical and actual tuberculosis. The former, too, is not necessarily microscopic, but may be a clinically demonstrable or even large process. In this connection we must always answer the questions: Is the tuberculosis active or quiescent? Is there any reason to believe that the person's tuberculosis will be affected by treatment? Such well—often robust—patients form a considerable group of the present tuberculosis hospital and sanatorium cases, especially the long-stay patients. They are not all tramps by any means, but often the permanent unfortunate victims, first of other people's ignorant advice and urging, and later of enforced idleness and institutional life. Too many have learned that the easiest and pleasantest life for them is as cases of tuberculosis. To get rid of them and the first class is the largest problem at present. Dispensary or home hospital supervision with, if possible, a yearly country vacation, would probably accomplish all that is done at the present time, and would go a long way to kill the merited reproach of creating

loafers. Patients come under observation for many reasons. To assume that all need some treatment or to send all who will go to some institution, because that is the easiest way to be rid of them, or is good insurance for the diagnostician, is unjustifiable. They should be told of the lack of necessity for present treatment, advised when to return, and forced to earn their own living. Many people seem to go on the principle that this is the one thing that should never be done. No one charged with responsibility therefor has any right to maintain them at the public expense.

The problem of employment for the handicapped is difficult, but we do not solve it, in fact only create a greater one when we place these patients in hospitals or sanatoria. If those who could support themselves were made to do it, and those who could not were induced to contribute by their work in tuberculosis homes, we would be nearer to an answer to the question.

Right at this point I can take up the question of segregation. At the present time I do not believe that we have a sufficient basis, either in public opinion, medical science, or in our knowledge of the extent of tuberculosis, to consider segregation purely as such, a necessary, justifiable, or practical measure. If in the light of fuller information such a plan is adopted, let it be done intelligently and with proper consideration of all the factors involved. At the present time it is used as an excuse for maintaining at high cost in tuberculosis institutions all sorts of cases and persons who have no other reason for being there—a perfectly absurd action when we consider that there is no way to determine whether the number so immured constitute one-tenth or one-ten thousandth of the total. Under these circumstances, I believe it to be absolutely unjustifiable to retain a case for no better reason, unless it be of the malicious sputum positive type to be held as a prisoner. There is no assurance that a dollar so spent is not absolutely thrown away. If the plans which I have outlined here were carried out we might incidentally segregate all who could be, so there is no profit in carrying the argument further at this point. I certainly believe we would segregate more than we do at present if we fostered the idea of care until death, rather than by keeping all patients in a state of expectation of the day of cure or dismissal, and creating the general atmosphere that treatment is temporary.

4. That there is among the many cases of tuberculosis a large fraction, early and late, who require treatment for their disease for varying, often long, periods, and are entitled to the best treatment that medical science knows, at the public expense, just as much as does the patient suffering from any other disease or injury; that their interests shall not be compromised by the means apportioned being frittered away in a wholly illogical fashion; that there are many kinds of tuberculosis, and that we should not rob the case who requires and will get results from treatment, for the sake of those who will not, any more than we would hesitate to spend money on, or would take any less care of, or use any less effort to relieve a case of sciatica, because there happened to be plenty of paralyzed persons to look after according to other standards. For those persons, that is, those definitely ill from tuberculosis, in an acute condition, including exacerbations and terminal stages in chronics, not comprehended in the previous exclusions, and for tuberculous persons suffering from other acute conditions, the tuberculosis sanatorium-hospitals and hospital-sanatoria should be reserved. The last mentioned demand treatment for their intercurrent diseases under such circumstances that they will not constitute a danger to others, because of their having tuberculosis. The tuberculosis, however, should not be allowed to dominate the picture or determine the length of treatment, except as would any other complication. However, not every tuberculosis hospital can be manned and equipped to treat all conditions met in a general hospital, and often it would be better to isolate tuberculosis cases with acute conditions in general hospitals, just as we do contagion, but especially in large cities, tuberculosis hospitals prepared to treat any acute condition are desirable. I have used the names "sanatorium-hospitals" and "hospital-sanatoria" advisedly, because the vast majority of tuberculosis cases which offer for treatment are neither incipient nor terminal, but belong in the great middle class, or second stage. This, curiously enough, is lost sight of in planning institutional care. I think that every tuberculosis institution should be a combination of hospital and sanatorium, with marked predominance one way or the other. This would mean an intelligent recognition of the fact that most of those to be treated are border-line cases, so to speak, and would provide the means for properly classifying and handling them all. Let us hope, too, that some day the last tuberculosis institution will take down the sign "No Readmission." If any patient ever was entitled to treatment as often as he got ill, that one is the one suffering from tuberculosis. It is typically cyclic in its course. What I state with regard to tuberculosis hospitals and sanatoria being reserved for the acutely ill, I do not wish to have interpreted as meaning that it is the only form of treatment adaptable to them. Because of the unfortunate effect of idleness on many persons, especially the working class, the desirability of trying out home treatment in suitable cases before sending to sanatoria should always be taken into account; that is, we should at least show some conservatism. It is most important to be sure first that our patient has tuberculosis—entirely too many diagnoses are made without sufficient basis—and, secondly, that granting he has tuberculosis, that it is from that that he is suffering. Tuberculosis patients, like other persons, have acute conditions like colds, and chronic conditions like malaria, and may require treatment only for them.

Of inapplicable, high-sounding, empty schemes to meet the criticisms of the present state of affairs, we have had plenty. The classification noted here is comprehensive enough to cover all possibilities, but very definite.

To some extent the second, third and fourth classes interweave, and the transition from one to the other is not always sharply defined. The patient must of course always get the benefit of the doubt, but we have here a good working program. Hand in hand with the medical aspect of this question goes that of the social classification. If the medical classification noted above is carried out, the social classification is largely solved. Experience shows that the great majority of undesirables belong to the vagrant, alcoholic, and chronic types. The question must not, however, be considered settled by this alone. What we want to do is to get the self-respecting, self-supporting man and woman, who is usually the one with a family, into the hospital, and this can be done only by having hospitals for

them and them alone. There is no occasion to be apologetic. They are just as much entitled to freedom from contact with persons of dirty habits and nasty minds as they are to clean beds. There is too much sentimentality and waste of effort on the good-for-nothing. They need no champions, but the decent do. Incidentally, I might mention that the riff raff are unhappy in respectable company, and one can kill two birds with the one stone by giving them the agreeable companionship of their fellows. Let us have a strict social classification in our sanatoria and hospitals by all means, and for the chronics, too, for if almshouses are of many kinds and degrees, from the proud old ladies' home to our needful but sorry Blackwell's Island institutions, why not the tuberculosis homes as well? The patient will almost naturally find his or her own level; assisting those who do not is a comparatively small affair. This is not only for their best interest and comfort, but, happily, the best action for the community.

In conclusion, I would say that I believe that the cause of the present state of affairs is, firstly, the unfortunate tendency of physicians to regard the whole question of the classification of tuberculosis cases settled when they tag the patient first, second, or third stage, forgetting that other classifications are often more important, and, secondly, of the artificial element in the antituberculosis propaganda now so widespread. Many persons realizing its many manifest absurdities, have yet remained silent, believing that in the long run the good to be derived in the form of public interest was a justification; but, personally, I never could see any profit in it, except to those who were making it their business or pleasure. Results tell, and to my mind the result of this propaganda has been to get the whole thing into a fine mess and impose a trying and unpleasant task of radical change on other shoulders. Now is the time for plain speaking. The question is essentially a medical one, and the stimulus to reform has got to come from the medical men who know tuberculosis. No matter if a lot of financially interested or well-intentioned persons are going about in a great state of excitement demanding that all cases of tuberculosis be treated, and hustling cases of all sorts into institutions, simply because tuberculosis can be proved or made likely in their case; there is no reason for permitting this to continue, no matter how hard put they may be to find a substitute activity. Let us enlighten their ignorance. If they want to help in an intelligent, sensible handling of the subject, well and good; if not, it will doubtless get along without them. At all events, if the present state of affairs is the result of their efforts, the sooner they are suppressed the better. Medical men know the facts and need not hesitate to stand up and speak out, and, if for no higher motive than personal interest, it is wise to do so, for sooner or later, like any other fraud, it will be found out. The question is here germaine: "Has New York City tuberculosis accommodation enough?" In any such estimate we must take account of the probable large increase in the use of the city's tuberculosis hospitals and sanatoria by the better class poor. They will not go to them under present conditions, but probably would if what I advocate was done. No greater good could follow the adoption of this program than to have them take advantage of the means provided, from which we are now apparently doing our best to automatically exclude them. Even with this increase, I think it probable that there is tuberculosis hospital and sanatorium accommodation enough; certainly there will be with the enlarged Sea View. What are needed are tuberculosis homs and provision for tuberculous tramps and alcoholics. Every disease is worthy of effort and expenditure in proportion to the effects of its morbidity and the size of its mortality. Tuberculosis ranks high in both, and provision of public funds on this account should therefore be large; but what is chiefly required is intelligent use of what we have. More may be found necessary, but there is no profit in spending any more on tuberculosis institutions, if it is to be spent without any greater reference to ordinary common sense than at present.

THE OCCUPATIONAL FACTOR IN DISEASES OF WOMEN.

CHICAGO.

PROFESSOR OF GYNECOLOGY, LYOLA UNIVERSITY MEDICAL SCHOOL. ATTENDING PHYSICIAN, HOUSE OF THE GOOD SHEPHERD.

SOCIETY is vitally interested in woman in her capacity of wife and mother and cannot regard complacently any arrangement of human affairs which will unfit her for these functions. Owing to the increasing numbers of women seeking employment outside of the home under conditions which may prove detrimental to health, the demands of childbearing and the laws governing that function remaining unchanged, a study of the effects of the new conditions upon both mother and child becomes necessary.

There is an extensive literature on occupational diseases and accidents from the employer's, the sanitarian's, the economist's, and the underwriter's standpoint, but there is little or nothing from the gynecologist's or obstetrician's.

In recent years there has been a great deal published in the current magazines, and especially in the British military journals, regarding the physical degeneration of the race. In our offices and dispensaries every day we hear the older women scoffing at their daughters' lack of endurance and boasting of the long hours of hard labor they themselves had endured when young. Is it not more than possible that in the overwork of the mothers might be found the cause of the weakened stamina of the daughters, or that the stock which furnishes our soldiers, largely the sons of working women, owes its deterioration to the same cause?

That women do not well endure the strain and hardships of industrial occupations is shown by the low birth rate, and the high death rate, and the frequent subnormalities both in size and weight which characterize the children of working mothers.

The statistics of the Leipsic Krankenkasse show that abortion occurs seven times more frequently in working than in nonworking women, that premature labor is six times as prevalent, and that the various accidents and complications of pregnancy and labor, as hyperemesis, placenta previa, ectopic gestation, premature detachment of placenta, hemorrhage, and uterine inertia are three times as frequent.

On account of her more delicate physique, a woman is not fitted for work requiring long-continued physical endurance. A woman under twenty cannot work continuously for ten hours a day in the most sanitary shop without serious injury or without

jeopardizing her chance of future usefulness as a woman. Neither her mind nor her body is fully developed, and the long hours, the monotonous work, the chronic exhaustion, the often unhygienic surroundings, to say nothing of the strain of existence on insufficient pay, are not conducive to physical or moral well-being.

Eight hours a day of ordinary work without undue nervous tension is enough to tax the strength of the average fully matured healthy young woman, yet in America 48 per cent. of all women workers are under twenty years of age and a large proportion of these are compelled by driving necessity to work at top speed for ten or more hours a day.

It is a question how much ill health among working women is due to injurious trade conditions and how much to outside factors, as poor or insufficient food, bad housing, unsuitable clothing, or vicious habits, but a little inquiry into both home surroundings and working conditions will enable one to form a reasonably correct opinion in any individual case.

Night work is particularly injurious, not only from the exhaustion incident to the long hours, the use of artificial light, and the absence of any possibility of recreation or relaxation, but also from the practical impossibility of obtaining sufficient sleep in day time. In shop practice it has been found that a year's unrelieved night work will break down physically and nervously all but the strongest girls.

Labor-saving machinery has added to the burdens of the working woman since the machine is now used as a means of speeding up production at the expense of the worker's health and strength. For example, the machine is set at a point where only by taxing every nerve to the limit can the operator keep pace. This effort causes a breakdown much sooner than does heavier work without the strain.

In certain of the hand trades, piece work is used as the lever for speeding up. Among tobacco workers, a stogy maker receives from 11 to 15 cents a hundred for rolling stogies. In some shops if she can roll over a thousand a day she gets an extra cent a hundred. In certain cracker factories, girls receive a cent a dozen for wrapping and sealing the packages of crackers with a bonus of ten cents offered if they can wrap over a hundred dozen a day, an almost impossible task. For sewing covers on boys' base balls, girls are paid 5 cents a dozen with hunger as the incentive to keep up the speed.

Certain trades are especially undesirable for women, such as those requiring long-continued standing, working in a stooping or bent position, lifting heavy weights, operating heavy machines, violent treadle work, or exposure to extremes of temperature, steam, dust, poisonous dusts and vapors, etc.

Women do not bear well the strain of long continued standing, as is required of sales girls, press feeders, and a large proportion of laundry and factory workers. This fact is so generally recognized that most States have laws requiring employers to furnish a reasonable number of seats for their female employees. Employers differ widely in their estimates of what constitutes "a reasonable number."

Prolonged standing not only exhausts the worker but it places an unnecessary strain on the arches of the feet and on the ankle, predisposes to curvatures of the spine, and is a factor of considerable importance in the development of downward and backward displacements of the uterus, of pelvic congestions, and of the various menstrual disorders. Varicose veins of the vulva and legs are common in young women while varicose veins and ulcers are even more common in older women.

In girls from 14 to 20 years old, prolonged standing and violent treadle work, such as is required in operating stamping and perforating presses, foot-power printing presses, and certain laundry machines, there is a noticeable effect upon the development of the pelvic bones.*

At this age the pelvic bones are not hard enough to withstand the almost constant pressure of continuous standing or the repeated impacts of treadle work. Prolonged standing of itself is undoubtedly responsible for a considerable percentage of simple flat and justominor pelves while the constant use of one leg in violent treadle work may readily cause a variable degree of oblique contraction together with a slight curvature of the spine. The lesser degrees of rachitic deformity may also develope in the same manner as the result of the mechanical factors just mentioned combined with a slight rachitis not uncommon in the underfed and ill-nourished factory girl.

In operating machinery where the girl stands on one foot and works a treadle with the other, the weight of the body being balanced on one leg, the pelvis gradually tips, being lower on the supported side, while the spine develops a compensatory scoliosis. At the same time the thrust of the supporting femur against the acetabulum tends to force the pelvic wall upward, backward, and inward and a marked oblique contraction may result. The younger the worker the greater the deformity.

In lifting heavy weights and in doing any kind of work requiring excessive muscular effort, the lungs are forcibly inflated and the abdominal muscles and diaphragm rigidly contracted. This causes a sudden violent increase of intraabdominal pressure, which, frequently repeated, may result in displacements of the pelvic organs, in the formation of hernias, and in abortion.

On the other hand, work requiring long-continued sitting bent over a machine or table, as in the sewing trades, watch factories, stogy and cigar making, coil winding, etc., is not devoid of harm. The bent position not only interferes with breathing but causes an injurious pressure on the lower abdomen, obstruct portal circulation, and is an important factor in the development of hemorrhoids and obstinate constipation so prevalent among these women. Among operators of foot-power sewing machines excessive menstruation is almost universal while in the sedentary factory trades anemia, chlorosis, tuberculosis, endometritis, sterility, and abortion are very frequent.

*Based on the external measurements of 826 working girls, all white, from 16 to 25 years of age and mostly nonpregnant. Cases of normal transverse diameters with an external conjugate of 18 cm. or less were classed as flat pelves. With an external conjugate of 18 to 20 cm. the case was classed, pending an internal measurement, as a possible flat pelvis. Of the 826 examined, 51 showed an external conjugate of 18 to 20 cm. while 43 showed a diameter of less than 18 cm. Of these 8 showed an interspinous diameter equal to or greater than the intercristal. 44 showed symmetric diminution of all diameters, 31 showed a difference of more than one cm. between the right and left oblique diameters, 18 showed a difference of more than 2 cm. between the right and left oblique diameters, while in 4 there was a difference of more than 3 cm. In 108 nonworking girls of approximately the same ages, 3 showed conjugates of 18 to 20 cm. one of 17½ cm. In 3 the pelvis was uniformly contracted, and in 2 there was a difference of over 2 cm. between the right and left oblique diameters.

Among tobacco workers, especially the makers of cheap cigars and stogies, who do their work either at their homes or in sweatshops, the girls are usually underpaid, overworked, crowded into filthy, unventilated rooms, the air of which is filled with clouds of the almost impalpable dust of the dried tobacco. Nasal and bronchial catarrh, conjunctivitis, and tuberculosis are very common while endometritis, menstrual disorders, and abortion are abnormally frequent.

In laundries, canneries, cracker factories, and preserving establishments the workers are exposed to extremes of temperature. In all of these the heat, the insufficient ventilation, the physical exhaustion, and the abrupt change at night from the superheated workrooms to the comparatively cold air outside renders these workers particularly liable to rheumatism, pneumonia, tuberculosis, and heart troubles.

In laundries the operation of the body ironer and the cuff press is the most harmful from the gynecologist's standpoint. Here the operator is not only working in a hot steamy air vitiated by the fumes of partially burned gas, but she is compelled at the same time to do the most violent form of treadle work.

The body ironer consists essentially of two heavy revolving metal cylinders, the upper one heated by means of gas jets in its interior, the lower one padded but not heated. The garment to be ironed is placed on the padded roll and forced by treadle action against the heated roll. To operate the reversing mechanism a second treadle action is necessary. With the left foot the operator bears heavily on the first treadle to force the rolls together. This pressure must be strong and continuous for the instant it is relaxed the lower roll drops. To reverse the direction of the rolls, the operator balances herself on one treadle and forces down the second, the weight being rapidly shifted from one treadle to the other until the garment is ironed. This work requires continuous, heavy, fatiguing muscular exertion. It is practically impossible for a girl weighing less than 170 pounds to run one of these machines, and an additional ten or fifteen pounds is an advantage rather than a detriment.

For operating cuff presses much younger girls are employed. Here the girl places a cuff on a padded saddle-shaped head and presses a treadle to force this head against a heated steam chest. A second kick causes the head to drop back, the cuff is turned and the process repeated. To iron a single cuff requires four distinct pressures on the treadle, and to hold her job a girl is expected to turn out at least 175 cuffs per hour.

Among operators of the body ironer uterine displacements, hernias, endometritis, and abortion are prevalent, while cuff-press operators, partly on account of their greater youth and partly on account of the difference in the character of the work, show an excessive number of pelvic deformities, menstrual disorders, and leucorrheas.

The operation of foot-power machines, where the machine is run by an alternate heel and toe pressure, as the ordinary sewing machine, results in a persistent pelvic congestion, characterized by excessive menstruation, dysmenorrhea, hemorrhoids, and backache. A number of gynecologists have taken advantage of this condition by prescribing a reasonable amount of work on the sewing machine for the relief of scanty menstruation.

Among the trades in which women are employed are a number in which there is daily contact with poison in one form or another. Of these so-called poisonous trades, those involving the use of lead and arsenic are the most important.

Lead is used in a multitude of industries, such as the manufacture, handling, and use of paints, the making of electric accumulators, printers' type, tin plate, the glazing of pottery, the polishing of glass, the manufacture of artificial gems, the weaving of lead-dyed yarns, china decorating, the manufacture of agate ware and enameled signs, etc. In all of these trades lead poisoning is of frequent occurrence. The inhalation of lead contaminated dust frequently causes respiratory troubles as the result of mechanical irritation of the respiratory mucosa, but poisoning results only from lead that is actually swallowed.

Women are much more susceptible to this poison than men, and young women are more susceptible than old. In women also the condition is much more serious than in men. The first evidence of plumbism is the appearance of a bluish discoloration along the gums, due to a deposit of lead sulphide in the tissues. This is followed by colic, obstinate constipation and a gradually increasing pallor. Later there is paralysis of certain groups of muscles, most often those of the wrist. Nephritis is usually present in well-developed cases. In addition to these symptoms in women there are headache, partial blindness, hysteria, coma, and sometimes insanity. A characteristic and very obstinate form of eczema occasionally develops.

Women in the lead trades are especially liable to abortion, and it is very seldom that one of these women gives birth to a healthy, well-developed, full-term child. A knowledge of this fact having become popularized in England cases of acute plumbism are occurring with increased frequency in the non-working classes.

Should a woman with lead poisoning give birth to an apparently healthy child, the latter will usually die before it is a year old. Should a nursing mother develop lead poisoning, the baby must be weaned at once, as the lead in the mother's milk will be sufficient to poison it.

Chronic arsenic poisoning is often unrecognized, but is of rather frequent occurrence in dye workers, makers of artificial flowers, zinc workers, trimmers in wholesale millinery shops, carpet weavers, and wall paper makers. The poisoning may be due either to the inhalation of arseniuretted hydrogen or to the swallowing or inhalation of arsenical dust or its contact with the skin.

When the poisoning is due to arseniuretted hydrogen, the symptoms begin almost immediately with shivering, weakness, headache, and collapse. Within the next twenty-four hours the urine becomes red or reddish brown from the presence of dissolved blood pigment. This is followed, if not accompanied, by a deep coppery jaundice. In severe cases death follows in from two to ten days. In mild cases the patient may recover, though the recovery is very slow and tedious. This form of poisoning occurs usually as an accident in the manufacture of zinc salts and in certain stages of the manufacture of galvanized iron. It is due to the unsuspected contamination of the zinc with arsenic.

The common form of arsenic poisoning is due to inhalation, swallowing, or contact with some form of arsenic. The skin becomes irregularly pigmented, the nails loosen, ulcers and eczematous patches appear on exposed parts of the body. Sore

throat, conjunctivitis, and nasal catarrh are usually present, while digestive disturbances, loss of appetite, vomiting, diarrhea, nervous symptoms, paresthesias, anesthesias, muscle weakness, and paralysis are not unusual. In addition to these symptoms deep, stubborn, punched-out ulcers frequently appear on the genital mucosa. Similar genital ulcers have also been observed in chronic mercurial poisoning, especially as it occurs in felt workers.

In the felt industry nitrate of mercury is used to increase the felting qualities of the rabbit fur used in making the best grades of felt. In addition to the genital ulcers already mentioned, these workers show severe inflammations and ulcerations of the respiratory mucosa, as the result of the inhalation of particles of lint saturated with the mercury salt. The teeth become blackened and corroded, the gums retracted, and not infrequently the molars fall out. These women also show a characteristic tremor known in the trade as hatter's or felter's shakes.

In both mercury and arsenic workers abortion, endometritis, menstrual derangements, and nervous disorders are very prevalent, but not to so great an extent as in the lead industries.

Considerable numbers of women are employed in cleaning establishments where naphtha is used. These women suffer from headache, vertigo, nausea, and vomiting. At first the symptoms are similar to those of acute alcoholism and disappear when the sufferer goes out into the fresh air. The irritating action of the vapor on the respiratory mucosa soon results in a chronic bronchitis, while the taste of naphtha in everything eaten soon causes a distaste, if not an actual loathing for food. Starvation results in malnutrition and profound anemia. Later the sight becomes weakened and there is a distinct loss of muscle power. Mental depression and hallucinations are of rather frequent occurence, while abortion, sterility, dysmenorrhea, and amenorrhea are exceedingly common.

In the rubber industry many of the employees are subjected to the fumes of carbon disulphide used in vulcanizing. While the carbon disulphide process is cheap it cannot be made safe and the poison is one to which women are exceedingly susceptible.

Industrial carbon disulphide poisoning is usually more or less chronic in character and is due to the long-continued inhalation of minute quantities of the vapor. After a variable time the worker begins to suffer from violent headaches, giddiness, and lassitude. The body is cold, the skin smarts and tingles. Later, a stage of excitement supervenes, during which the patient is nervous, irritable, and absolutely unable to sleep. Following this is a progressive diminution of muscle power, muscular twitching, and incoordination. The muscles waste and paralysis in varying degrees appears. Vision is usually diminished. Mental deterioration commences, the memory fails, perception is blunted, speaking becomes difficult; anemia is marked. Sterility and menstrual derangements are usually present.

The chronic form of this poisoning is rarely fatal. The mild cases run a tedious course, but gradually recover on change of occupation. The severe cases may improve as the result of a complete change, but the mental and physical deterioration is usually permanent.

Aniline poisoning is occasionally seen in this country and is usually of rather more interest to the urologist than to the gynecologist. Crude anilines are generally contaminated with arsenic, and as a result the majority of cases of aniline poisoning reported in America are not aniline but arsenic poisoning.

Genuine aniline poisoning is occasionally encountered among the makers of black inks and among the dyers of black woolens. The poison is absorbed through the skin or by inhalation. It acts on the red corpuscles of the blood causing a discharge of the coloring matter and the formation of methemaglobin. The symptoms are headache, dizziness, muscular weakness, cyanosis, and in severe cases air hunger. Nephritis appears early and persists long after the disappearance of all other symptoms. In chronic aniline poisoning tumors of the bladder, both malignant and benign, are of remarkably frequent occurrence. In the European aniline works a thorough cystoscopic examination is required in all cases of suspected poisoning.

For want of time only a small number of the more important occupations having a direct bearing on pelvic disease have been considered. Many occupations directly affecting the pelvic organs have been omitted because of the small number of women engaged therein.

The trades involving grave constitutional deterioration but not directly affecting the pelvic structures, as the sewing and textile trades with their frightful toll of tuberculosis, core making, and the steamy trades with their pneumonia, rheumatism, and cardiac disease, and the speeded factory trades with their physical and nervous breakdown, have of necessity been considered outside the scope of this paper, yet these conditions constitute a grave menace to the welfare of the race and urgently demand further study as to their effect on the health of women workers, on their reproductive capacity, and on the children they bear.

15 East Washington Street.

SOME OCULAR MANIFESTATIONS OF AURAL DISTURBANCES AND THEIR INTERPRETATION.

By J. A. HAGEMANN, M.D.,

PITTSBURGH, PA.

A SCRUTINY of the approved text-books dealing with otology leaves the impression upon one that the signification of eye symptoms due to conditions in the ear is not adequately elucidated by the authors. An endeavor to supplement this deficiency is the motive of the present paper. Teleologically considered, ocular nystagmus, resulting from aural pathology or experiment has been an enigma, the solution of which has taxed the perseverance and defeated the ingenuity of numerous investigators. It is uncontroverted that ocular nystagmus may be induced by several cranial lesions other than aural, but they are intentionally disregarded herein, as their consideration would transgress the limits and purposes of this paper. It is a matter of common empirical knowledge that the familiar rotation tests, caloric tests, etc., either establish or disprove labyrinthine involvement, but the raison d'être remains abstruse.

The nerves, or branches of some of them, which are to be considered in scrutinizing the supply of the eye-moving muscles whose concordances with aural irritations serve as our index, are the third, fifth, fourth, sixth, and seventh. The third, or

motor oculi, supplies all the muscles of the orbit except the superior oblique and the external rectus. The motor oculi emerges at the anterior border of the pons and passes forward diagonally to the clinoid process of the sphenoid bone. The nerve divides into two rami, which enter the optic cavity by way of the superior orbital fissure in communion with the trochlear, and the first ramus of the trigeminus (ophthalmic), and the abducens nerves, in order to reach the ocular muscles innervated by them, and to supply the levator palpebræ superioris muscle. The three rami of the fifth or trigeminus nerve (ophthalmic, supramaxillaris, and inframaxillaris) all enter the Gasserian ganglion. The first division of the ophthalmic ramus of the fifth, the lacrymal, supplies the lacrymal gland and the conjunctiva, terminating in the integument of the upper eyelid. The trunk of the trigeminus becomes discernible at the basal surface of the pons. The anterior (motor) root makes its exit between the anterior decussating fibers of the pons, and is almost covered by the posterior (sensory) root. Both roots lie in close apposition and presently enter Meckel's cave. This cave is formed by a separation of the dura mater into its two layers, and is located upon the upper and anterior surface of the temporal pyramid. Near the apex of the pyramid formed by the temporal bone there is a depression lined with the external layer of the dura, which assumes the functions of periosteum. The Gasserian ganglion rests in this depression, and is covered by the inner layer of the dura. The fourth, or trochlear nerve, emerges immediately behind the corpora quadrigemina, winds round the outer side of the crus cerebri, immediately above the pons Varolii, pierces the dura mater in the free border of the tentorium cerebelli, and passes forward through the outer wall of the cavernous sinus toward the orbit, where it supplies the superior oblique muscle. The sixth nerve (abducens) springs from the corpus pyramidale near the pons or from the pons itself. The deep origin has been traced into the medulla. Before leaving the posterior cranial fossa the abducens approaches the base of the brain, and courses subdurally to the cavernous sinus, whose posterior wall it pierces. After traversing the sinus, the nerve enters the orbital fossa by way of the superior orbital fissure. It supplies the external rectus muscle. The auditory nerve (portio mollis of the seventh pair) arises from the floor of the fourth ventricle, and is also involved with the gray matter of the medulla. In conjunction with the facial nerve, the auditory, after a short course along the base of the brain, enters the internal auditory meatus. The two nerves shortly separate, however, and the auditory continues its course to divide into its two ramifications, the cochlear and vestibular nerves, whose titles sufficiently indicate their destination.

The foregoing condensed and necessarily incomplete summary of the origin, course, and distribution of the several nerves which participate in the various reactions brought about by the involved relations between the ear and eye is merely introduced for the purpose of refreshing the reader's memory upon the anatomical relations embraced. By the aid of illustrations contained in almost any volume on anatomy, the salient anatomical points will be brought out in relief, and simplify what at first glance might appear a difficult or complex subject. A vinculum between the cortical centers controlling optic muscular movements and the medullar and allied optical centers has not been unequivocally demonstrated. As a result of experimental and pathological observations, theoretical association-centers have been interpolated, whose apparent location is in the large ganglionic cells situated about the corpora quadrigemina. From these cells a tract arises which descends toward the medulla, and by reason of its relationship to the nuclei of the several nerves which supply the eye muscles, may be regarded as a reflex center. If we accept this view, we are supplied with a practical hypothesis to interpret the significant ocular manifestations of auricular irritation. The impression propelled from the semicircular canals, be it experimentally or pathologically aroused, is borne along the course of the auditory nerve. At or near its source the conjectural association centers convert the impressions into motor impulses, which are projected along the several nerves supplying the ocular muscles. Not emanating from conscious, cortical direction, it is cognizable that the resultant muscular movements should be signally different from those under the guidance of conscious cerebration. Yet these involuntary, graphic manifestations are anything but erratic. By painstaking intentness one is enabled to localize approximately certain aural lesions, and to corroborate or refute diagnoses based upon other signs and symptoms. Confusion has resulted from the indiscriminate use of the term "reflex" as applied to the subject under discussion. It should be borne in mind that ocular evidences of aural pathology may be manifested in three diverse ways. Firstly, as a reflex; secondly, as a transmission, and thirdly, as an effect of a direct impairment of a nerve in transit. The familiar ocular nystagmus is a true reflex, as the impression is borne to a distributing center, whence it is propelled via a different nerve to its ultimate destination.

To enter upon a description of the manifold ocular responses to auricular irritation would lead us too far afield, and would be but a repetition of text-book lore. Suffice it to assume that the medullar auricular centers, having received an impression of unusual disturbance in the semicircular canals, at once take on an exaggerated responsivity. While in this discordant state their normal functions are notably perverted. Being intimately associated with the neighboring ocular muscle centers, they readily impart their perturbation to these, whereby more or less involuntary, spasmodic contractions of the ocular muscles and consequent nystagmus are produced. Even the voluntary ocular movements imposed by the cerebral cortical centers may be imperfectly performed; a turning of the eyes laterally or perpendicularly resulting in a decided nystagmus, whose direction and form are contingent on the location of the irritation in the semicircular canals.

The second manner by which a correlation between the middle ear and the eye may be established is through the instrumentality of the trigeminus nerve. During the course of a case of acute purulent otitis media severe pain in the eye may be experienced, accompanied with the symptoms ordinarily characteristic of conjunctivitis. This is not a reflex, but a transmission, as the impulse is not borne centripetally to a cerebral or cerebellar center, thence to be propelled centrifugally along the course of another nerve, but passes from one branch to another of the same nerve by a circuitous route, and the resultant paroxysm is in reality a

distal manifestation of the enkindling excitation. The impulse passes along branches of the trigeminus, beginning at the nerve-filament that supplies the tensor tympani muscle. This filament is derived from the optic ganglion, which vinculates with the auriculotemporal nerve, a branch of the inferior maxillary, itself the third division of the fifth nerve. The impulse then traverses the first or ophthalmic division of the trigeminus to its lacrymal branch, where the afflictive evidence of the distant irritation becomes perceptible through pain, lacrymation, photophobia, etc.

The third and least prevalent way in which correlation between an aural pathology and ocular manifestations may be occasioned is by direct impairment or ravage of a nerve that supplies one or more ocular muscles. Generally and collectively speaking, the trochlear, motor oculi, and abducens nerves and the Gasserian ganglion lie over the apical end of the temporal bone. The abducens is particularly vulnerable here, because it courses in a fibrinous or bony gutter or duct from the outer side of the inferior petrosal sinus to the cavernous sinus, and at this point hugs the bone for perhaps 1 cm.

As already mentioned, the Gasserian ganglion lies in a shallow concavity near the apex of the temporal bone. Occasionally a temporal bone will contain a chain of pneumatic cells extending from the vicinity of the middle ear to the apex. It is conceivable, and has been necroscopically demonstrated, that an infective process may traverse this channel, perforate the surface of the bone, and invade the neural fibers lying in close apposition thereto. Injury or destruction of the abducens nerve would be announced by paralysis of the external rectus muscle; a condition readily elicited. On attempting to look toward the paralyzed side, the affected eye will stop centrally, the while its mate will turn toward the inner canthus. Trauma of the Gasserian ganglion would be heralded by conjunctivitis, atrophy of the cornea, and other grave signs separate from the eye. Paralysis of the trochlear nerve has been reported. This would be evidenced by loss of function of the superior oblique muscle.

The import of pupillary contraction and expansion as a result of diseases of the ear is not well understood. Apparently similar conditions will, in different patients, produce diametrically opposite reactions. Inequality of the pupils, particularly in children, should in the absence of palpable causes, prompt one to search for aural pathology.

While the foregoing discourse is far from being exhaustive, the hope is cherished that it may prove of assistance to some other in unraveling several of the tangled skeins which occasionally come into our hands.

A CLINICAL REPORT OF THE SUCCESSFUL USE OF EMETINE IN THE CONTROL OF HEMORRHAGE FOLLOWING NASO-PHARYNGEAL OPERATIONS

By JOSEPH WEINSTEIN, M.D.,

NEW YORK.

The following report of 12 cases in which emetine was successfully employed to control or prevent hemorrhage during and after operations upon the nose and throat is not submitted by the writer as a positive statement that emetine will control all such cases of hemorrhage, but as an invitation to his fellow workers in the field of rhinology and laryngology to cooperate with him in the "trying out" of a remedy, which, if found to be efficacious, will be of inestimable benefit to mankind.

Pelletier, in 1867, separated from ipecacuanha its emetic principle and named it emetine. Paul and Cownley in 1894 isolated its two crystalline alkaloids, emetine and cephaeline. Since then emetine has been most successfully employed in several fields of medicine. Captain Edward P. Vedder, U. S. A., and Dr. Leonard Rogers of Calcutta have demonstrated its use in cases of amebic dysentery, in which they are supported by such men as Chauffard, Dopter, Lukis, Low, Allen, Friedenwall, and Zobel.

Rogers has also demonstrated its uses in cases of amebic hepatitis, and with others its value diagnostically, the true amebic dysentery reacting to emetine within three days after its injection hyperdermatically.

Renault has recently employed it in the treatment of cholera, obtaining, in a severe epidemic, 73 per cent. of recoveries. Flandin and Joltrain used emetine successfully in the hemoptysis of tuberculosis, and French physicians, for hemorrhage occurring in typhoid and uterine hemorrhage following cancer.

Dr. Joseph P. Prestley employed it successfully in controlling a case of obstinate nosebleed, and Dr. William Sellers in a case of persistent hemorrhage from the gums. In 1914 Barrett and Smith demonstrated its use in pyorrhea alveolaris and also state that emetine hydrochloride given subcutaneously is likely to prove curative in many cases of tonsillitis. In this they are supported by Middleton.

No mention seems to have been made thus far in the literature of emetine having been previously employed in nasopharyngeal surgery, and in using the drug in this field the writer has been influenced entirely by his own studies and observations. The action of emetine upon hemorrhage has not, as yet, been satisfactorily explained. It does not coagulate the blood nor does it lower the blood pressure, but apparently acts directly upon the capillaries by closing them up.

The writer is mindful of the small number of cases which he is submitting in testimony of the efficacy of emetine to control hemorrhage of this class, but trusts that this report may be a nucleus about which many other reports of the successful employment of emetine in this field will rapidly grow.

Case I.—Miss K. P. Tonsillectomy under local anesthesia. Injection—emetine hydrochloride one-half grain, half an hour previous to operation. No hemorrhage.

In the following series of 11 cases the emetine was given immediately *after* operation.

Case II.—Mrs. H. Complete obstruction of both nasal fossa, disease of the ethmoid, nasal polypii. Bled profusely when operated upon for polypi several years previous, to the extent that posterior packing was necessary for 48 hours. Operated on at present time for polypi and ethmoid (one side). Practically no hemorrhage.

Case III.—Mrs. M. Chronic suppurative ethmoiditis. Clinical history of profuse bleeder; weight 260 pounds. Practically no hemorrhage. Packing was removed after six hours with slight oozing, which subsided in twenty minutes.

Case IV.—Mr. H. Deviated septum. Removed posterior ends of inferior turbinates. Packing removed next morning. No bleeding. This patient had had previous nasal operation when bleeding continued for five days.

Case V.—Mr. S. Tonsillectomy (double) under ether anesthesia. No hemorrhage.

Case VI.—Mr. G. Severe hemorrhage following tonsillectomy. Operation was performed by another physician, followed after five hours by a severe hemorrhage. Every means had been employed to check it. Hemorrhage ceased in ten minutes after one injection of emetine.

Case VII.—Mr. J. G. Capillary bleeding from septum extending over a year's time. Would stop at times, but always recurred within two or three days. Various treatments unsuccessfully employed. Since injection of emetine three weeks ago there has been no recurrence of bleeding.

Case VIII.—Mrs. G. Deviated septum. No hemorrhage. This case is particularly interesting as when packing was removed there was not *one drop* of blood.

Case IX.—Miss F. Double middle turbinectomy, followed by profuse bleeding. Controlled in ten minutes after one injection of emetine.

Case X.—Mrs. G. Hypertrophied margins of both inferior turbinates removed, also posterior ends of both inferior turbinates. No bleeding followed. Patient attended theater same evening. Profuse bleeding next morning when packing was removed. A second injection of emetine was given previous to repacking. Hemorrhage ceased in five minutes and repacking was not necessary. This is the only case in which the writer found it necessary to give a second injection of emetine.

Case XI.—Mrs. R. Double middle turbinectomy. Packing removed from one side of nose after eight hours. No bleeding. No hemorrhage the next morning when the packing from the other side was removed.

Case XII.—Mr. L. Posterior ends of both inferior turbinates removed, and right middle turbinectomy. No hemorrhage when packing was removed next morning.

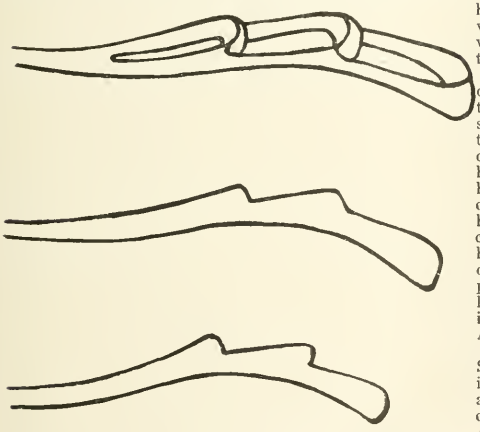
In each instance ½ grain emetine hydrochloride was given hypodermatically.

261 Central Park West.

THE ROMEO THREE-BLADED UTERINE CURETTE.

By PASCAL ROMEO, Ph.B., M.D.,
KANSAS CITY, KANSAS.

The curette which I have designed is intended, so far as it is possible, to eliminate the disadvantages of the ordinary curette and to make thorough and



uniform curettage a safe operation, even at the hands of those who are not very familiar with the required technique.

The curette has three blades arranged in stepping formation, as can be seen by the accompanying illustration, along the convex side of the instrument, in such a way that during the curettage all three blades will engage simultaneously on the inner surface of the uterus. The concave shape of the uterus conforms to the convex shape of the curette and with the three points of contact of the same, the danger of perforating the womb is avoided and the curettage is made thorough, since the instrument is prevented from cutting too much or too little into the uterine tissues by its anatomical points of contact. In the puerperal uterus, where there is retention of membranes on account of abnormal adhesions, the common curette, even the dull one, may cause undue trauma and may not always free the uterine cavity from foreign bodies.

In this case the three-bladed curette renders a very great service, as the work of the same is controlled by the association of all three blades and their anatomical arrangement.

My personal experience in a large maternity home, also the testimonial of many obstetricians and gynecologists at home and abroad, have determined me to present the three-bladed curette to the medical profession at large, as it may be interested in its general practice, especially where a specialist is not always available. The curette is manufactured by Becton, Dickinson & Co. of Rutherford, N. J.

346 North Fifth Street.

Medicolegal Notes.

Grounds of Liability in Malpractice Cases.—In an action against a physician for malpractice, based on his negligence in placing the plaintiff's swollen and inflamed leg in a plaster cast so tight as to impede circulation and cause blood poisoning, the jury rendered a general verdict for the plaintiff, and specially found that it was the customary practice to so incase an injured limb; that the plaintiff continued to suffer intense pain after the cast was placed on her leg; that gangrene might be produced without blood poisoning; that a tight bandage would not produce blood poisoning without first producing gangrene; that pain existing before the cast was put on was due to a sprained ankle; that a disease of the bone substance, in which pus was present, existed; and that neither bone of the plaintiff's leg was fractured nor split. The jury did not find that her hip was not dislocated. It was held that the special verdict was not in conflict with the general verdict, with all legitimate inferences from the evidence within the issues authorizing a recovery.

The question of negligence, or failure to exercise ordinary skill and care in the treatment of any particular case, does not depend upon the professional skill and learning of the physician, but is to be determined from a consideration of his acts, conduct, omissions, and treatment in the particular instance. If he possessed the highest degree of skill and learning in his profession, and failed to exercise the care and diligence required by the law in treating the patient, his skill and learning could not shield him from the consequences of such negligent treatment. On the other hand, if he did not possess the skill and learning required by the legal standard, but his treatment in the particular instance was proper, he could not be held liable for the want of such skill which resulted in no injury to the patient.—Longfellow v. Vernon, Indiana Appellate Court, 105 N. E. 178.

Sales by Itinerant Vendors.—The United States Supreme Court holds that prohibiting the sale by itinerant vendors of "any drug, nostrum, ointment, or application of any kind intended for the treatment of disease or injury," as is done by Louisiana Laws 1894, Act No. 49, section 12, does not violate the equal protection or due process of law clauses of the Fourteenth Amendment to the Federal Constitution, although the sale of such articles by other persons is permitted.—Baccus v. Louisiana, 232 U. S. 334, 34 Sup. Ct. 439.

Basis of Hypothetical Question.—A hypothetical question, to an expert called for the plaintiff in a malpractice case, as to a treatment being proper to reduce a fracture, may be based on what the plaintiff's witnesses alone testify was done, and need not contain what the defendant claims was done.—Duffy v. Charters, Michigan Supreme Court, 147 N. W. 541.

MEDICAL RECORD.

PHYSICOCHEMICAL STUDIES ON THE BLOOD.

FROM the viewpoint of diagnosis the greatest emphasis has been placed upon the morphology of the blood and comparatively scant attention has been paid to the physicochemical changes that occur in this medium under normal and pathological conditions. The studies of Hamburger on the osmotic and ionic properties of the blood formed the basis for a large number of investigations along this line, most of which have been concerned with seeking the application of the fundamental laws of physics to the vital fluid. The majority of the studies of the physical properties of the blood have been concerned with the so-called resistance of the red corpuscles to hypotonic salt solutions.

A comprehensive research into the nature and degree of the last-mentioned phenomenon has been made by Gottfried Holler (*Zeitschrift für klinische Medizin*, Vol. 81, Nos. 1 and 2). The resistance of the red blood cells is regarded as a complex phenomenon dependent upon the actual resistance of the protoplasmic framework and the osmotic pressure of the intracellular fluid. The author devised a special technique for studying the degree of this resistance under various conditions. The main features of this technique consist in the preparation of two similar series of tubes containing solutions of sodium chloride and arranged in an order according to the descending concentration of the solution. Suspensions of red blood cells are added to both series of tubes; but the suspension added to one of the series is first repeatedly washed in physiological salt solution. The tubes are allowed to stand for twenty-four hours and are then examined against a white background. The red corpuscles form a sediment at the bottom of the tubes. The tube in which the supernatant liquid first shows the slightest red tinge is regarded as the one which indicates the minimum degree of resistance of the red blood cells to hemolysis.

With this technique it was found that under normal conditions the minimum resistance for unwashed red blood cells is indicated by the tubes having a saline concentration of 0.44 to 0.48 per cent. In case of the washed corpuscles the resistance is lower. Holler used this method in studying the resistance of the red blood cells in a wide range of diseases. Thus in febrile conditions generally there is a diminution in resistance, a fact attributed to the reduced alkalinity of the blood. On the other hand, in typhoid fever and pneumonia the globular resistance is increased as the result of the withdrawal of sodium chloride from the red blood cells to supply the demands of the exudate and the setting free of chlorine ions which have an important effect upon the osmotic pressure of the cellular content. In jaundice there is an increased resistance, while in severe anemia, as in chlorosis, the resistance is diminished. In the primary hemolytic anemias there is evidence of a biochemical peculiarity which favors the early lysis of the red blood cells.

The technique elaborated by Holler lends itself readily to routine laboratory work on the blood, and promises results of eminent diagnostic value, particularly in the realm of hematology.

THE MECHANISM OF URINARY EXCRETION.

THE newer studies of the functional capacity of the kidneys have been undertaken with reference to this organ as a whole, rather than with reference to any of its constituent parts. To what extent these studies will serve to throw any light upon the long-disputed problem as to the relative rôles of the Malpighian bodies and of the convoluted tubules is still a matter for conjecture. At any rate, the older physiological data will require thorough overhauling with the aid of the newer functional tests. The old controversy has waged about the hypothesis of Bowman which held that the vessels of the glomeruli act as filters and permit only the water of the blood to escape, while the convoluted tubules excrete the urea and the salts; and the hypothesis of Ludwig which held that the glomeruli excrete the entire urine with all of its constituents while the concentrating of the urine is regulated by the cells of the convoluted tubules which absorb water to a considerable extent from the urinary excretion.

Erich Leschke has applied the newer methods with the aid of dyestuffs in testing the relative merits of the above theories and reports his results in the *Zeitschrift fur klinische Medizin*, Vol. 81, Nos. 1 and 2. He notes that previous investigations along this line have shown that the greater part of the coloring matter injected into the blood is eliminated by way of the convoluted tubules, while the rôle of the glomeruli with respect to these dyestuffs is still problematical. The author's investigations has confirmed those made by others, namely, that foreign substances such as the salts of ferrocyanic acid and iodine are excreted by the cells of the convoluted tubules. None of these salts has been detected in the cells of the glomeruli. With the aid of original histochemical methods Leschke has shown that the important urinary constituents are all excreted by the cells of the convoluted tubules. The glomeruli excrete water together with a percentage of sodium chloride and of other salts corresponding to that in a physiological salt solution. If large amounts of these salts and of urea and purin bodies are injected into the body, the excess is eliminated by the convoluted tubules, while the glomeruli continue to excrete the fluid

having the equivalent concentration of physiological salt solution. The specific activities of the cells of the convoluted tubules control the concentration of the urinary outflow.

The important researches of Leschke tend to substantiate the original theory advanced by Bowman. To what extent the cells of the uriniferous tubules are capable of effecting a resorption of water is uncertain. But any hypothesis regarding this is unnecessary, in view of the specific activities of the cells which excrete the urinary constituents.

EXPERIMENTS ON THE ETIOLOGY OF ECLAMPSIA.

A LARGE number of theories have been advanced to explain the origin of eclampsia, but the one which seems to hold greatest sway is that which attributes this condition to an intoxication. E. T. Hull and G. L. Rohdenburg (*American Journal of Obstetrics and Diseases of Women and Children*, December, 1914) performed a series of experiments upon rabbits, based upon the hypothesis that eclampsia is due to an excess in the maternal circulation of the products of the digestion of fetal protein. It is pointed out that with the exception of bacterial disease and intentional injection, pregnancy is the only condition in which complex proteins are introduced into the general circulation parenterally.

As a result of the above experiments it was found that ferment-active homologous protein introduced parenterally causes an extensive degeneration of the liver and, as a rule, but slight degeneration of the kidney. These changes in the rabbit correspond to those observed in the case of the eclamptic human female. If the homologous protein is boiled so as to destroy the enzymes and is then introduced parenterally it causes but slight lesions in the liver; but, on the other hand, it causes marked lesions in the kidneys, as evidenced by the large amounts of albumin and casts in the urine. The animals die in convulsions and coma, manifesting all the symptoms of human eclampsia. The injection of leucin, a product of autolysis, causes a marked degeneration of the liver in rats and rabbits.

The authors believe that an overload of fetal elements is thrown into the circulation and is autolyzed with the formation of an excess of leucin. This injures the hepatic vessels with consequent thrombosis, cloudy swelling, local necrosis, and more or less complete autolysis of the liver cells. The renal changes are regarded as probably due in part to other products of autolysis and perhaps also to protein fractions incompletely broken down by the liver. The liver may be damaged to a surprising degree experimentally before clinical symptoms appear in the animals.

Hull and Rohdenburg believe that the hemorrhages and the convulsions are due not to extensive hepatic changes but to the renal lesions. They attribute considerable importance to albuminuria as a clinical sign, since severe renal degeneration appears to be the predominant lesion. The suggestion is made that a negative protective ferment and the determination of the leucin content of the blood in a pregnant patient may be of diagnostic value.

THE PASSING OF STATE QUARANTINE.

WITH the change of administration of the New York State Government, strong hopes are entertained that the quarantine station at this port will before long be transferred to the care of the Public Health Service; indeed, it is said that the arrangements for this transfer are already being discussed. If this is done it will be but a short time before the anachronism of city or State quarantines will be definitely at an end. At present there are only three places in the country where this condition prevails, and at one of these, Baltimore, the quarantine service is practically under federal control, for the Public Health Service maintains a quarantine at Cape Charles which all vessels for Baltimore must pass before entering the Chesapeake. The other local quarantine is at Boston, and we learn from the *Boston Medical and Surgical Journal* that the transfer of the control of this station is under serious discussion, having been already approved by the Boston Association for the Relief and Control of Tuberculosis, the Norfolk and Suffolk Districts of the Massachusetts Medical Society, the Boston Homeopathic Medical Society, and the Boston Finance Commission. The transfer of these three quarantine services to the control of the federal government would be in the interests of public health, of administrative economy, and of good politics.

AN OVERLOOKED FACTOR IN THE DEVELOPMENT OF EUROPEAN WAR TETANUS.

THE frequency of tetanus wound infection in the present war, especially among the German troops, has already given rise to an extensive journal literature characterized largely by efforts at placing the responsibility where it really belongs. We see at one or two hospitals 100 per cent. of recoveries, in others medium mortalities, while in some others, despite all precautions, the death rate approximates 100 per cent. A factor occasionally invoked is wet weather or some other condition of the milieu, while even the *genius epidemicus* of old writers is again up for discussion. It seems quite evident that the German surgeons have never been informed as to some work done this year in the Hygienic Laboratory of our Public Health Service. The work was rather unpretentious—only a record of experiments on small laboratory animals; but the evidence went to show that tetanus bacilli could circulate in the blood freely without forming any toxin until they came in contact with some special local disease process which appeared at once to activate them. Any staphylococcus suppuration might answer for this purpose, and, strange to relate, the presence of quinine in the tissues after a subcutaneous injection of the latter showed similar powers. It is held in standard works that the tetanus bacillus is merely fixed by the peripheral nerves and never enters the circulation. This is probably true so far as virulent bacilli are concerned, but in regard to a latent form this possibility seems never to have been worked out in mankind.

CHAULMOOGRA OIL IN LEPROSY.

CHAULMOOGRA oil has of course been employed in the treatment of leprosy for some little time by different methods, and in various combinations. Dr. Victor G. Heiser, surgeon, U. S. Public Health Service and Director of Health for the Philippine Islands, has, however, been conducting investigations

with regard to the value of a mixture of Chaulmoogra oil, camphorated oil, and resorcin used hypodermically in the treatment of leprosy. A report on the matter was read at the eleventh annual meeting of the American Society of Tropical Medicine, held in Boston, Mass., May 29 and 30, 1914. The summary and conclusion of this report are published in Public Health Reports, Oct 16, 1914, and the conclusion is briefly as follows: The present stage of the development of the treatment does not warrant a claim that anything like a specific for leprosy has been found, but experience does show that it gives more consistently favorable results than any other that has come to the attention of Heiser and his co-workers. It produces apparent cures in some cases, causes great improvement in many others, and arrests the progress of the disease in almost every instance. The treatment is apparently equally efficacious in all forms of the disease, that is, the tubercular or hypertrophic, the anesthetic, and the mixed.

Ground Squirrels.

Ground-squirrel plague, although not identical with true bubonic plague, can be communicated by the animal infected to man without the intervention of fleas or biting insects. This fact is pointed out in a paper contributed by Dr. Derrick T. Vail of Cincinnati, in describing a case of "squirrel plague" conjunctivitis in man, to the *Ophthalmic Record* for October, 1914. Like the bovine tubercle bacillus, the squirrel plague bacillus, while communicable to man, is distinct from the human plague bacillus and less virulent in its effects. Dr. Vail shows that the case described by him was beyond doubt one of squirrel plague ophthalmia and, so far as he is aware, the first case of the kind ever recorded. In Public Health Reports, December 11, 1914, Dr. J. O. Lyon, surgeon, U. S. Public Health Service discusses the economy of ground squirrel extermination, which seems to prove conclusively that these animals are exceedingly destructive. Thus from the points of view of both health and economy ground squirrels are pests whose extermination is indicated.

News of the Week.

Belgian Physicians' Relief Fund.—The following contributions were received by the Committee of American Physicians for the Relief of the Belgian Profession during the week ending January 9, 1915:

E. G. M.	$10.00	G. E. L.	$5.00
L. M. W.	5.00	E. E. K.	10.00
A. T.	10.00	A. M. C. O.	100.00
J. G. R. M.	25.00	D. S. M.	10.00
J. C. T.	25.00	C. M. B.	1.00
L. C. F.	10.15	M. C. M. S.	25.00
E. T. F.	10.15	H. M. S.	10.00
F. W. S.	10.00	E. H. M.	5.00
G. L. H.	25.00		
Total			$296.30
Previously reported			$662.50
Grand total			$958.80

It has been thought best to make public acknowledgment of contributions by initials only, but we feel we are violating no confidence in stating that the initials A. M. C. O. and M. C. M. S. stand for the Academy of Medicine, Cincinnati, Ohio, and the Marion County (Ohio) Medical Society. These two bodies have set a good example which might be followed with great advantage to our suffering Belgian colleagues by other medical societies—local, State and county—throughout the country.

The Gorgas Prize Medal.—Dr. Harold Hays, Secretary, writes that a prize, to be known as the Gorgas Medal, to be given yearly in honor of Surgeon-General Gorgas, has been established by the Association of the Medical Reserve Corps, U. S. Army, New York State Division. This medal is open to competition to members of the Medical Corps of the United States Army, the Medical Reserve Corps of the United States Army, and the Medical Corps of the organized militia. Officers may submit papers on any subject of a medico-military nature. General Gorgas has appointed the following board of officers to act upon papers submitted: Colonel Charles Richard, Lieut.-Col. Champe C. McCulloch, Jr., and Major Eugene R. Whitmore, Army Medical Corps. These officers are members of the faculty of the Army Medical School and will have sole authority to appoint the time that papers are to be submitted, and to pass upon the merits of the papers. All inquiries should be addressed to one of these officers.

Dr. Otto Kiliani of this city, who is now serving with the Bavarian army in charge of a lazaretto at the front, has received the iron cross for conspicuous services.

Dr. Charles F. Stokes, recently Surgeon-General of the U. S. Navy, has been offered by the New York City Board of Inebriety the position of superintendent of the city farm colony for inebriates in Orange county. The farm colony occupies 800 acres near Warwick and now has thirty-two inebriates under treatment. A temporary dormitory is being erected, so that soon fifty-six more men can be accommodated.

Dr. S. Lewis Ziegler has been appointed Director of Public Health and Charities of Philadelphia in succession to Dr. Richard H. Harte, resigned.

A Japanese Red Cross Party passed through New York this week on its way to England, sailing hence on Wednesday. The party consisted of two surgeons, seventeen nurses, and an interpreter. The chief surgeon was a former member of the medical corps of the Japanese army, Dr. Suzuki, and his assistant, Dr. T. Oshima. Miss Yamamoto was in charge of the nurses. Three Red Cross units have been sent to Europe, one each to Russia, France, and England.

Medical Lawmakers.—The Portland *Argus* says that twelve members of the present State Legislature of Maine are medical men, five in the Senate and seven in the House. The physicians in the Senate are Drs. Aaron J. Fulton of Aroostook, A. M. Garcelon of Androscoggin, Henry M. Moulton of Cumberland, G. Gilmore Weld of Penobscot, and Wallace N. Price of Sagadahoc. Those in the House are Drs. Albert W. Plummer of Lisbon Falls, Richard T. Leader of Lewiston, Augustine B. Libby of Merrill, Isaac D. Harper of Gorham, Elmer J. Morrison of Bar Harbor, Cecil E. Wasgatt of Deer Isle, and Adelbert Merrill of Belfast.

Street Accidents.—According to the report of the National Highways Protective Society, 290 persons were killed on the streets of Greater New York by automobiles during the past year. This is a decrease. The figures for 1913 were 302. In deaths by trolleys there were 100, as against 108 in 1913; 128 were killed by wagons, whereas 170 met their deaths in that way in 1913. Outside of the city of New York, where most of the cars are operated by owners, there were 310 persons killed by automobiles in the State. In 1913 there were 149. The report also shows that 61 persons were

killed by trolley cars and 32 by wagons. The corresponding figures for 1913 were 79 and 32. Buffalo's record alone was 72 deaths by automobiles.

A Federal Narcotic Law.—On December 10 the House of Representatives passed a law putting many restrictions on the sale of coca leaves or opium or any of the alkaloids and other preparations made from them. The bill provides that "every person who produces, imports, manufactures, compounds, deals in, dispenses, sells, distributes, or gives away" any of these drugs shall register with the collector of internal revenue of his district and shall pay an annual tax of one dollar. Drugs can be sold or given only on the production of a written order of the purchaser or recipient which order shall be preserved by the seller or giver for two years. Any one giving a prescription for any of these drugs must write it upon a special form in duplicate and preserve the duplicate for two years to show it to any authorized government official upon request. The provisions of this act apply to the United States and all its territories and possessions, and go into effect March 1, 1915. We presume this law is constitutional since it has been enacted by both houses of Congress and signed by the President, but it seems to leave to the individual States no power to regulate the licenses of drug sellers within their own boundaries unless to place still further restrictions upon the traffic.

"Boston Medical and Surgical Journal."—Announcement is made that this journal has been incorporated under the laws of Massachusetts as a charitable institution, the business management of which will be in the hands of Mr. Ernest Gregory acting for the incorporators, with Mr. W. M. Leonard, the former publisher, as consulting manager. Dr. E. W. Taylor has retired from the office of editor-in-chief and the editorial staff now consists of the following physicians: Dr. Robert M. Green, Editor-in-Chief, Drs. Walter L. Burrage and Frederick T. Lord, acting for the Massachusetts Medical Society. Drs. Walter B. Cannon, Harvey Cushing, David L. Edsall, Reid Hunt, Roger I. Lee, Allan J. McLaughlin, Robert B. Osgood, M. J. Rosenau, E. C. Streeter and E. W. Taylor constitute the Consulting Editorial Board. The *Journal* is now the official organ of the Massachusetts Medical Society and the only weekly State medical journal in the country.

Prosecutions for Illegal Practice in Utah.—Out of ten prosecutions for the alleged illegal practice of medicine in Utah during the past two years there has been but one conviction, according to the biennial report of the State Board of Medical Examiners, recently issued. The remedy for this unsatisfactory condition, the report says, lies in simplification of court procedure and insistence on performance of duty by county and district attorneys. The report shows that ninety-seven licenses were issued by the board during the two years.

Free Dental Clinics for School Children.—The system of Dental Clinics now conducted by the Department of Health of this city is a direct extension of the first Municipal Dental Clinic founded and maintained through the energy of the Honorable Peter T. Barlow, Magistrate of the City Court. The clinic was situated at 449 East 121st street, New York City. The Department of Health took over this clinic about April 1, 1913. Subsequently a completely equipped dental clinic which had been operated by the Brooklyn Bureau of Charities was donated to the Department of Health and installed at 124 Lawrence street during the summer of 1912. Additional dental clinics have been established as follows: 330 Throop avenue, Brooklyn; 1249 Herkimer street, Brooklyn; 580 East 169th street, The Bronx; 164 Second avenue, Manhattan, and 689 Bay Street, Staten Island.

Gifts to Science and Charity.—The will of the late Mrs. Mary Anna Palmer Draper gives $50,000 to the New York Polyclinic Hospital, $25,000 to the New York Skin and Cancer Hospital, and $25,000 to the laboratory of surgical research of New York University, of whose medical department Dr. Henry Draper was at one time dean.

Mrs. Luther S. Johnson of Lynn, Mass., has given $100,000 to the Lynn Hospital corporation to be used for the erection, furnishing, and partial maintenance of a nurses' home.

"School and Society" is the name of a weekly educational journal which begins publication with the new year under the editorship of Dr. J. McKeen Cattell, professor of psychology in Columbia University and the Teachers College, editor of *Science*, *The Popular Science Monthly*, and *The American Naturalist*. It is announced that the journal will follow the general lines that have made *Science* of service in the sciences, cooperating with publications in special fields, aiming to become the professional journal for those engaged in the work of our lower and higher schools, and to be of interest to the wider public for whom education is of vital concern. The first number opens with an article by Dr. Charles W. Eliot, president emeritus of Harvard University, entitled "Educational Evolution." Dr. G. Stanley Hall discusses the teaching in our schools of the war, and President W. T. Foster of Reed College commends the "State-wide campus" of the modern university. There are departments devoted to discussion and correspondence, quotations, books and literature, educational research and statistics, societies and meetings, educational events and educational notes and news.

The Medical Pickwick is the title of a new journal for medical readers, yet not a medical journal, the first number of which bears the date, January, 1915. The magazine is published at Saranac Lake, N. Y., and Dr. Walter M. Brickner is the editor, which fact is a guarantee that the journal will not be lacking in humor. But the aim of the publication is not alone to be humorous, it is to be entertaining as well, to treat of all matters, except scientific, relating to medicine. The first number contains a foreword by Fielding H. Garrison; "The Singer in the Snows" (referring to Stevenson's life at Saranac), by Stephen Chalmers; "The Brownings," by J. Louis Ransoshoff; "Isle de Blackwell," by John B. Huber; "Modern Medical Writers," by Davina Waterson; "The Author's Complaint," by Walter M. Brickner; "The Pickwick Medical Society," by Ira S. Wile; "The Medical Pickwick," by Samuel W. Kelley; "An Old English Sign-board," by Eli Moschcowitz; "Nut Raising for Doctors," by Robert T. Morris; "Two War Poems," by Henry C. Coe; "To Johannes Brahms in Vienna," by Theodor Billroth; "Therapeutics of Two Hundred Years Ago," by Alice Chadwick; "Incubation at the Temple of Epidaurus," by Lucille Kohn; "Julius Pagel," by Major C. Seelig; unsigned articles on "The Man Himself, Abraham Jacobi," "Original Account of Mountain Sickness," "The Surgeon in the Field Hospital," "William Hunter," "Anecdotes of Dr. John Radcliffe," and a great number of anecdotal

and humorous paragraphs, original and scissored. Dr. Brickner has opened a new vein in the mine of medical lore, and it gives good promise of leading to pay dirt.

Medical Society Elections.—Medical Society of the County of New York.—At the meeting held November 23, the following officers were elected: *President*, Dr. Howard Lilienthal; *First Vice-President*, Dr. Frederic E. Sondern; *Second Vice-President*, Dr. George O. Stewart; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. Daniel S. Dougherty; *Treasurer*, Dr. Charles M. Richardson.

Physicians' Motor Club of Philadelphia.—At the annual meeting held December 5 the following officers were elected for the ensuing year: *President*, Dr. S. Leon Gans; *First Vice-President*, Dr. John J. Robrecht; *Second Vice-President*, Dr. Charles A. E. Codman; *Third Vice-President*, Dr. Charles R. Haig; *Secretary*, Dr. Howard A. Sutton; *Treasurer*, Dr. Lewis H. Adler, Jr.; *Directors*, Dr. Ellwood R. Kirby and Dr. W. D. Robinson.

College of Physicians of Philadelphia.—At a stated meeting held December 6, Dr. John B. Deaver read a paper entitled "Gastric Uulcer," and the following officers were elected for the ensuing year: *President*, Dr. James C. Wilson; *Vice-President*, Dr. Richard H. Harte; *Secretary*, Dr. Francis R. Packard; *Treasurer*, Dr. John B. Roberts; *Honorary Librarian*, Dr. Frederick P. Henry.

Obstetrical Society of Philadelphia.—At the annual meeting held December 7, the following officers were elected for the ensuing year: *President*, Dr. Daniel E. Longaker; *First Vice-President*, Dr. John A. McGlinn; *Second Vice-President*, Dr. F. Hurst Maier; *Secretary*, Dr. Edward A. Schumann; *Treasurer*, Dr. William E. Parke.

New York Neurological Society.—At a meeting of this Society, held January 5, the following named officers were elected: *President*, Dr. William M. Leszynsky; *First Vice-President*, Dr. E. G. Zabriskie; *Second Vice-President*, Dr. F. Kennedy; *Corresponding Secretary*, Dr. J. R. Hunt; *Recording Secretary and Treasurer*, Dr. C. E. Atwood; *Councillors*, Drs. L. P. Clark, Frederick Tilney, Alfred S. Taylor, I. Abrahamson, and S. E. Jelliffe.

The Orleans Parish (La.) Medical Society, at its annual meeting, December 12, 1914, elected the following officers: *President*, Dr. W. H. Knolle; *Vice-President*, Dr. Lucian H. Landry; *Second Vice-President*, Dr. R. C. Lynch; *Third Vice-President*, Dr. Henry Daspit; *Secretary*, Dr. Paul T. Talbot; *Treasurer*, Dr. George H. Upton; *Librarian*, Dr. Howard D. King; *Additional Members, Board of Directors*, Dr. Chas. N. Chavigny, Dr. Maurice J. Gelpi, and Dr. E. L. King.

American College of Surgeons.—At the third convocation of the College, held in Washington, D. C., November 16, the following officers were elected: *President*, Dr. J. M. T. Finney of Baltimore; *First Vice-President*, Dr. W. W. Chipman of Montreal; *Second Vice-President*, Dr. Rudolph Matas of New Orleans; *General Secretary*, Dr. Franklin H. Martin of Chicago; *Treasurer*, Dr. A. J. Ochsner of Chicago.

The Bexar County (Tex.) Medical Society, at its meeting on December 17, elected the following officers: *President*, Dr. Thomas Dorbrandt; *Vice-President*, Dr. Conn Milburn; *Secretary*, Dr. W. H. Hargis; *Treasurer*, Dr. L. B. Jackson; *Delegate to the State Medical Association*, Dr. C. D. Dixon; *Alternate*, Dr. R. L. Dinwiddie; *Censor*, Dr. Frank Paschal.

Obituary Notes.—Dr. Paul Fitzsimmons Eve of Nashville, Tenn, formerly professor of surgery and dean of the Medical Department of the University of Tennessee, died at his home, after a short illness, on December 26, aged 58 years. Dr. Eve was graduated from the University of Tennessee, Medical Department, in 1878, and from the College of Physicians and Surgeons, New York, two years later, and was immediately thereafter appointed a demonstrator of anatomy in the University of Tennessee, later becoming professor of anatomy, and still later succeeding his brother as professor of surgery and dean of the institution. He was a member of the American Medical Association, and a member and ex-president of the Tennessee State Medical Association, the Davidson County Medical Society, and the Nashville Academy of Medicine.

Dr. Leonard Melville French of Manchester, N. H., died December 21 at the age of 65 years. He was a graduate of the Dartmouth Medical School in 1873.

Dr. Samuel Livingston Howard, a retired physician of Louisville, Ky., died December 14 at the age of 67 years. He was born near Ghent, Ky., and was a graduate of the Ohio Medical College.

Dr. Miner C. Hazen, the oldest member of the Middlesex County Medical Association, died in Haddam, Conn., on December 26 at the age of 85 years. He was born in Agawam, Mass., and was graduated from the University of Michigan in 1855. He prescribed first in Middletown and in 1860 moved to Haddam where he remained in active work up to the time of his retirement some six years ago.

Dr. Emery E. Sherman of Independence, Iowa, died recently at the age of 79 years. He was born in Conway, Mass. In early life he crossed the plains a member of trains to and from California, but later took up the study of medicine, being graduated from the Rush Medical School in 1861. He then entered the army as assistant surgeon in a Missouri regiment and served until the end of the war, when he began practice in Palmyra, Wis. There he remained for twenty years and then removed to Independence where he practiced for twenty-three years.

Dr. F. A. Tillinghast died of pneumonia at his home in Arctic Center, R. I., on December 24 at the age of 72 years. He was born in Escoheag and was graduated in medicine from the University of Vermont in 1867. For many years he practiced in Norwich, Conn., but settled in Rhode Island in 1897.

Dr. Elisha H. Lyford of Dover, Me., died on December 20. He was born in Atkinson in 1840 and was graduated from the Medical School of Maine, Portland, in 1866. He practiced most of his life in Vinalhaven, removing to Dover about six years ago.

Dr. Clement Dietrick O'Leary, a practitioner in Providence, R. I., up to about three years ago, died of tuberculosis at the Wallum Lake Sanitarium on December 22. He was born in New Haven in 1864 and was graduated from the Medical Department of Columbia University, New York, in 1887.

Dr. G. Houston Chapman of Uniontown, Ky., died suddenly on December 18. He was born in 1849 and was graduated from the Jefferson Medical College, Philadelphia, in 1874.

Dr. E. R. Cogswell, a retired physician of Cambridge, Mass., died of pneumonia on December 22, at the age of 73 years. He was a graduate of the Harvard Medical School in the class of 1867.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ST. JOHN'S AMBULANCE AND RED CROSS SOCIETIES—SOME HOSPITALS IN CONNECTION WITH THEM—HOSPITAL SUNDAY FUND; ANNUAL REPORT—LIVERPOOL'S MILITARY MOVEABLE HOSPITAL—OBITUARY.

LONDON, December 26, 1914.

THE St. John's Ambulance Association and the Red Cross Society, at a time like this, naturally absorb much attention, and to them Queen Mary's Needlework Guild is supplying special requirements in the way of clothing of every description in addition to articles classed as medical, *e. g.*, gauze, iodoform gauze, lint, boracic lint, wool, cradles for bedclothes, and so on. A joint committee of the two societies is promoting the work and preventing overlapping as well as employing staff nurses and sisters, both for home and foreign service. Two hospital trains for service in France and Belgium have been subscribed for by the union of millions of the United Kingdom; one of them is nearly ready to proceed, can carry 358 wounded, and has a staff and personnel of 51; its fellow is being rapidly built. Both are constructed by English railway companies on specifications by the War Office. They will cost nearly £25,000, nearly all of which was procured by the society of millers within about three weeks of the resolution to provide them being adopted.

British Red Cross ambulances of various sizes are working at the front, and their value can scarcely be exaggerated. At Boulogne there are a number standing day and night with their orderlies ready to start on transport work. The society has also a voluntary Aid Department at Boulogne, consisting of nearly thirty persons, besides three fully trained hospital nurses. English forces are common enough at Boulogne, both as passers through and as visitors. At present the medical men are perhaps more numerous than usual. Among them Sir F. Treves has been over and was highly delighted with the transport arrangements by which the wounded are taken off from a train the moment of its arrival, to the wards or to the hospital ship with a speed which he calls "a revelation to those who have only seen horse or hand carriage in the removal of the sick." For their service he reports there are seven railway wagons completely fitted up on a platform siding, every detail having been worked out with the greatest care, the equipment being excellent, and "the order and method worthy of the highest praise." Those passing through are also supplied with food and other comforts. As many as 2,300 were one day so ministered to, and in about five weeks the total number reached about 30,000, " a fine piece of Red Cross work inexpensively administered and the very greatest boon to the poor fellows who reach the base after a long, exhausting journey." There are ten military hospitals at Boulogne and seven others, voluntary, but accepting military control; one has 270 beds and another 189.

At Wimereux, the British hospital has 102 beds with an *x*-ray department. There is also an Anglo-American hospital (Lady Hadfield's), with 100 beds, 20 nurses and 30 orderlies, under the St. John's Ambulance Association; an Australian hospital with 166 beds, the medical staff and nurses all from Australia—*x*-ray department here, too; a Canadian hospital and another for women (65 beds), are also in full work. At Calais the Baltic Hospital for Belgian soldiers has 105 beds and 11 motor ambulances. There is an annex for enteric cases (20 beds), and a clearing house by the railway station.

The annual meeting of the Metropolitan Hospital Sunday Fund was held on Tuesday. Sir C. E. Tritton presided and urged that to-day the hospitals of London had a greater claim than ever. In the wards of many of them were numbers of wounded soldiers who had fought for their country with a heroism and bravery that was the talk of the world. On returning disabled they were carefully tended in these hospitals. He hoped that every one would do his utmost to add to the comfort of these heroes on this saddest Christmas the world has known, following the example of the House of Commons which had laid aside all prejudices and party passions to rally round this effort.

The Venerable Archdeacon Brook Deedes in moving the adoption of the report expressed the satisfaction of the supporters that in this exceptional year the income was better than in the previous one by £400. In the coming one there would be increased demands, and they must take care that there should be no anxiety as to the provision of sufficient funds. The Rev. H. Harwood, in seconding the motion, said they were exceedingly grateful that so far they had not suffered on account of the numerous, unusual claims of other organizations. People were giving everywhere with more than ordinary generosity; it really seemed as if they were beginning to understand the luxury of giving.

The report was adopted and the Council was re-elected for the year 1915, in which the date of Hospital Sunday was fixed for June 13.

Liverpool is much interested just now in a proposal to equip and send to the front what her residents talk of as the "movable hospital." This is a military hospital of the most complete type with everything necessary for the treatment of the wounded and other urgent cases. It is constructed in sections and can be dismantled, taken to pieces and packed for removal in forty-eight hours, while on arrival it can be rebuilt and fitted ready for use in twenty-four hours. It will therefore be able to follow the forces, and, except in cases of hurried marches, can be located near the firing line. There are to be eight pavilion wards, each having accommodation for twenty-six patients. Dr. Nathan Raw and Dr. Jones of Liverpool will take charge of the hospital, with a nursing staff of forty obtained locally.

Deputy Surgeon-General William Henry Harris of the Indian Medical Service died on December 11 at Shanklin in his 85th year. He qualified in 1851, joined the Madras Medical Service in 1853, took M.D., St. Andrews, 1859. He reached the rank of Deputy Surgeon-General in 1881, having been a fellow of Madras University and professor of midwifery, as well as superintendent of the lying-in-hospital.

Another Indian medical veteran, Lieut.-Col. Edward Butler Ruttledge, who retired in 1889, has died at the age of 70.

Lieut.-Col. E. L. Maunsell served in the R. A. M. C. from 1880 to 1908. He was M. O. H. at Gibraltar for several years. He died on the 7th inst., aged 61.

Mr. Bernard Pitts, consulting surgeon to St. Thomas' Hospital and a pioneer in abdominal surgery, died on the 13th inst., aged 66. A bold, skillful and careful surgeon, he accomplished much, and his upright conduct kept him the full confidence of

the profession. His lectures at the Royal College of Surgeons on Affections of the Air Passages in Childhood were greatly appreciated.

PSYCHOPATHOLOGY OF THE WAR.

London, Dec. 24, 1914.

This has been anything but a merry Christmas for every one in England; not only has the war been conducted with the loss of thousands of good men, for its casualties are probably much greater than the Government is willing to admit, but all Northern Europe has been under water, and it has rained hard every day for more than a month—a record-making deluge which credulous people are inclined to ascribe to the heavy firing at the front. From all accounts the hardships and exposure, despite modern provisions for the betterment of the troops, are very great, and Napoleon's celebrated Russian campaign did not approach the conditions that exist to-day, and have for weeks. Men have fought for days in the trenches waist deep in cold water, and even the Highlander does not complain. As a consequence much rheumatism and pneumonia have prevailed in all the armies, and men have been consequently invalided.

So far as wounds are concerned, they are, as I have said in another letter, confined chiefly to the extremities, and the head injuries are ordinarily fatal. So much fighting has taken place in the trenches that there are comparatively few body traumata, excepting those due to the bursting of shells therein. A new feature of this war consists in the production of curious psychical conditions due to excitement, strain, or shock. Many of us who are familiar with the railway psychoses at home, will find their counterparts in the Western battle fields. There are, as ever, cases of traumatic insanity in predisposed subjects. The retreat from Mons is now being understood and recognized, as it should be, as the most awful incident of warfare of any age. It was simply continued carnage. When the British forces withdrew before the hordes of Germans who were suddenly thrown upon them, the mental shock was incredible. There was no cowardice, no rout, and the shattered forces, like the teeth of Cadmus, sprang from the ground to the astonishment of the admiring Germans, but the result was that many soldiers instantly became deaf-mutes. This was especially the case in the Seventh Division, which comprised hardened and brave troops who had fought in several previous wars. A considerable number of these men remain in this condition to-day and are being studied by several London neurologists, who say they have found a new kind of psychosis. They are apparently sane, but have received so sudden and severe a mental insult as to cause a complete inhibition of the faculties of hearing and speech.

Dr. Joseph Blake who is the practical head of the American Ambulance Hospital in Paris, tells me that there are not many new cases there of neurological interest, but many soldiers with wounds involving the peripheral nerves. I have seen and heard of strange cases of neuritis and consequent anesthesia—one of the ulnar nerve, caused by a blow of a piece of frozen dirt thrown out by an exploding projectile, which seems of frequent occurrence.

Besides the other admirable measures taken to preserve the health of the troops and to relieve the strain at the front, the military authorities are granting short leaves of absence which rarely exceed five days, and are spent in England. Of course, this surprises the Germans. It is already apparent that even a few days' absence from the hellish experience and anxiety in the field which is carried almost to the breaking point, will do much to improve the morale of the soldiers. I was told last week by a returned officer that the enemies' method of attack was to begin at one end of a trench and gradually drop big shells, advancing in fire surely but slowly, so that every man was keyed up, not knowing when his turn would come and what would be the result.

2. The Vesalian Spirit. L. S. Pilcher.
3. Analysis of Recoveries at the Psychopathic Hospital, Boston. T. H. Haines.
4. Subnormal Temperatures in Tuberculosis. A. K. Stone
5. Coccygodynia, Causes and Treatment. R. Duffy.

1. **Louvain and Its University.**—R. M. Green, in the opening address at the celebration by the Harvard Medical Society of the four hundredth anniversary of the birth of Vesalius, presents an account of the history of the University of Louvain, in which Vesalius received his early education and to which he returned to lecture on anatomy after he received his medical degree at Paris. The name of Erasmus is also associated with that of Louvain.

2. **The Vesalian Spirit.**—L. S. Pilcher, in the second address at the celebration referred to in the last article, points out that Luther in religion, Michael Angelo in art, Paré in surgery, and Vesalius in anatomy were all contemporaries and the products and exponents of the Renaissance. The peculiar qualities of Vesalius were energy, enthusiasm, contempt for authority, and a demand for personal demonstration.

3. **Recoveries at a Psychopathic Hospital.**—T. H. Haines analyzes a second series of one hundred recoveries at the Boston Psychopathic Hospital. He notes that the large number of patients suffering from serious disturbances of metabolism and at the same time insane but recoverable, demonstrates the unique field of service of psychopathic work and psychopathic hospital.

4. **Subnormal Temperature in Tuberculosis.**—A. K. Stone calls attention to the fact that at a certain period of tuberculosis, usually succeeding the active febrile stage, there is often a period when the temperature curve shows marked excursions in the subnormal, the temperature at no time rising above 98.6 degrees and rarely reaching this point. The patients are usually improving, but it takes very little to give rise to real febrile exacerbations. The period of subnormal temperature may last for weeks. Mild tuberculous infections frequently show a rapid change from a febrile condition to a subnormal temperature. This is particularly the case in tuberculous pleurisy when the fluid is removed. A persistent subnormal temperature is an almost unerring indication of tuberculosis.

5. **Coccygodynia.**—R. Duffy differentiates the vague pains about the coccyx which are present in various nervous conditions from true coccygodynia. In neurasthenia often, in tabes at times, in hysteria, and in traumatic neurosis pains in the sacral and coccygeal regions are complained of. But such pains are indefinite and dull rather than sharp, and there is not much tenderness of the coccyx. In true coccygodynia the pain is

always sharp and lancinating and caused by movements of the body or anus, or by pressure. The coccyx is exquisitely tender on rectal palpation. The pain is definitely located in the coccyx and does not radiate. The author believes that true coccygodynia is always of traumatic origin, there being an injury of the sacrococcygeal articulation or of the nerves in its neighborhood. Fracture or caries of the coccyx may account for some cases. As regards treatment, the statement is made that medical treatment is only temporizing. There are two forms of surgical treatment, excision of the coccyx and De Vésian's method of the injection of alcohol. The latter was described by Yeomans in the MEDICAL RECORD, August 22, 1914.

9. Primary Nasal Diphtheria. H. A. Schatz.

1. Pneumococcus Infection and Immunity.—R. I. Cole points out that there are different types of pneumococci, all of a single species, each giving rise to clinical manifestations of infection of special grades of severity. The mortality of pneumonia varies from 47 per cent. in cases caused by type III to 6 per cent. in cases caused by type IV. The infection caused by type III is, however, relatively infrequent. Butterfield and Peabody have demonstrated that methemoglobin is formed when pneumococci are cultivated in media containing blood. This suggests a possible explanation of the toxic action of pneumococci, and of other bacteria as well, on tissue cells.

2. The Psychical Aspect of Syphilis.—H. G. Klotz discusses the disturbances in mental equilibrium occurring in patients infected with syphilis. A negative serum reaction, under certain conditions, indicates a highly probable but not absolutely certain cure. The serum test under certain conditions, particularly in so-called latent syphilis, is likely to do more harm than good, and its application ought to be put under the rule of common sense. As long as uncertainty exists with regard to a definite cure of syphilis, the psychical aspect has to be taken into account, and the patient will have to rely, not only on the laboratory, but also on the confidential advice and sympathy of the physician who has closely watched the clinical symptoms and will also bear in mind the mental state.

3. Appendicitis Under Field Service Conditions.—A. W. Williams reports the results in fifty-two cases of appendicitis in which the patients were operated upon under field service conditions with United States Army troops. The author would change Deaver's expression, "cut well, sew well, and your patients get well," to "go in quickly, get out quickly, and your patients will get well quickly." The following points are regarded as favorable to early operation for appendicitis in the military service. The patient is, as a rule, a young able-bodied soldier. If by reason of any physical disability he is unable to perform his daily duties, he is required to go on sick report. When his name is entered on sick report, he has to be seen by the surgeon. So, if he is taken ill during the night, and delays going on sick report until next morning, not over twelve hours will elapse before his case is investigated. Owing to the discipline he is accustomed to in the military service, when told by a medical officer that he requires an operation, he usually accepts the decision without question. Over-solicitous relatives and friends are not present to urge delay. At a field hospital the medical officers live in camp, in tents adjacent to the wards, so consultants and assistants are always on hand.

4. The Psychology of War.—W. L. Howard believes that war is the outcome of sex instincts and their many modes of expression. He points out the distinction between the sexual instinct and sensuality, the former making for home, health, morality, and patriotism.

1. Institutions for Infants.—H. D. Chapin considers this subject under two heads: the hospital for the acutely sick infant, and the foundling asylum. The stay of an infant in a hospital should be as short as possible owing to the progressive loss of weight which generally occurs if the infant is not discharged shortly after the acute symptoms of its illness have subsided. Another disadvantage of the hospital is the danger of the spread of specific infections, and particularly by the ordinary ward infections as rhinitis, pharyngitis, tonsillitis, otitis media, bronchitis, bronchopneumonia, and vaginitis. The author would not encourage the multiplication of infants' hospitals throughout the country. Large wards and large institutions are undesirable. More can be accomplished with sick infants by home treatment than has ordinarily been supposed. As regards foundlings and abandoned infants, the boarding-out system offers a healthier physical environment than the infant asylum.

2. Typhoid Immunization.—L. I. Harris and M. L. Ogan record the results of the experience of the Health Department of New York City in typhoid immunization. This procedure is definitely preventive in all but a relatively insignificant few cases. In those subsequently affected it strikingly decreases the morbidity and the mortality. Severe reactions are rare, and are avoided by the following precautions: Never administer the vaccine to any but the healthy. To permit of slow absorption, avoid puncture of a vein, or intramuscular injection. Clean the syringe and sterilize the area for injection, using tincture of iodine for this purpose. Children especially are to avoid exposure to the sun following the treatment. Avoid administering the vaccine during the menses or pregnancy. Allow no hard work or indulgence in alcohol after the injection. Avoid reinjecting in indurated areas. Severe reactions have never left permanent injury. When the incubation period has begun, the time for antityphoid immunization has passed. Long exposure to overwhelming doses of typhoid bacilli (in those who are in close contact with cases and especially in epidemics), may nullify the immunizing powers of antityphoid vaccine, and an attack may therefore follow one or more injections. Chronic illness (tuberculosis, etc.), as well as debility

from other causes, fatigue, and exhaustion, predisposes to severe reactions. Injections after intimate and long exposure hasten the onset. For a period of at least two years, and possibly more, immunization is as effective in protecting from an attack of typhoid fever as is a previous attack of the disease itself. Recurrences may follow after a complete immunizing course of treatment, in exceptional instances in which debility and fatigue exhaust the resistant and defensive powers of the body, and when exposure to massive doses of typhoid bacilli exists.

3. **Mistaken Diagnosis in Hospital for Advanced Tuberculosis.**—J. E. Ash states that in the 198 necropsies performed in the Boston Consumptives' Hospital since its foundation, twenty-three cases, or 11.5 per cent., have been proved to be non-tuberculous, in so far at least that there was no active lesion. The points emphasized after an analysis of these cases are the following: A patient showing progressive loss of weight and strength, with cough, expectoration, and even hemoptysis and abnormal physical signs in the chest, is not necessarily in a hopelessly advanced stage of tuberculosis, but occasionally still amenable to treatment directed to the real cause of the symptom complex. Particular attention should be paid to excluding cardiorenal conditions and pneumonia with its sequelæ. One sputum examination, either positive or negative, should not be depended on to establish a diagnosis.

4. **Bitter Tonics and Gastric Secretion.**—A. J. Carlson finds that bitter tonics acting either in the stomach or in the mouth are practically without influence on the quantity of the secretion of gastric juice either in man or in the dog.

11. **Radical Removal of the Verumontanum.**—A. G. Rytina concludes that colliculectomy is a simple operation for the removal of the verumontanum. It is less liable to untoward complications and sequelæ than strong applications of silver nitrate or the thermocautery. The study of the pathology of the verumontanum is made easy, in consequence of which a therapy may be devised, based on science rather than on empiricism. Surface applications of mild antiseptic solutions seem to be irrational. Strong penetrative cauterant substances may have great therapeutic value in curing infections, but may do more harm than good, on account of the production of untoward complications or sequelæ. A straight-beaked colliculectotome lends itself to the removal of vegetations and polypi from any part of the anterior urethra.

2. A Case of Intestinal Obstruction, with Some Notes on Operative Technique. A. Webb Jones.
3. Stretchers for the Wounded in the Trenches. G. K. Aubrey.

1. **Problems in Mental Pathology.**—E. Goodall in the fourth of the Croonian Lectures discusses the application of the method of complement deviation in psychiatry, and also the study of the cerebrospinal fluid in this branch of medicine. He calls attention to the fact that the Wassermann reaction may be negative at a given test in both the serum and cerebrospinal fluid in certain cases of paresis. With the use of increasing strengths of cerebrospinal fluid amboceptor a positive Wassermann with 0.2 c.c. of a 1 in 10 solution indicates paresis, but a negative reaction with any strength up to even 1 c.c. of the pure fluid does not exclude this disease if only once obtained. Negative reactions with large amounts of fluid are not infrequently obtained in, at any rate, the more quiescent periods of the disease, or in slowly progressive cases. In such periods and cases the complement deviation method cannot be relied upon for diagnosis between paresis and cerebrospinal syphilis. As regards the value of the Nonne-Apelt test: in cases of undoubted paresis it is more often positive than the Wassermann test with the cerebrospinal fluid; it is obtained more consistently throughout the course of the disease; and it is more reliable as revealing the persistence of the disease in remissions. On the other hand, it is less reliable in diagnosis, occurring more frequently in cases of insanity which are not cases of either paresis or cerebrospinal syphilis. There is an absence or deficiency of complement in the cerebrospinal fluid in paresis and there is sometimes a deficiency, at any rate, of amboceptor. In these respects the fluid resembles that of non-paretics. In paresis complement is absent from the cerebrospinal fluid, which resembles that of normal persons in having no hemolytic properties.

British Medical Journal.

December 26, 1914.

1. Color Vision and Tests for Color Blindness. C. Devereux Marshall.
2. Colectomy for Intestinal Stasis. A. W. Sheen.
3. An Operation for Movable Kidney. G. S. Thompson.
4. Cockroaches. H. E. Shipley.
5. A Case of Tetanus Treated by Injections of Carbolic Acid P. Stewart and J. T. C. Laing.

1. **Color Vision and Color Blindness.**—C. Devereux Marshall calls attention to the fact that, although physiologists in general now regard the Edridge-Green lantern test as vastly superior to the so-called wool test as a means of detecting color-blindness, the latter test is still the one favored by the English Board of Trade. The wool test even in its improved form allows 50 per cent. of dangerous cases of color-blindness to pass. The essential merits of the Edridge-Green test are described by Halliburton as follows: "The Edridge-Green lantern is one of the best to employ; in it the intensity and color of the light and the order in which the colors are shown can be easily varied."

2. **Colectomy for Intestinal Stasis.**—A. W. Sheen reports four cases in which this operation was performed with one fatality. The operation is a serious one, requiring careful preparation of the patient and careful technique. It should be reserved for cases with marked signs and symptoms of stasis. In the author's experience it contrasts with many cases in which various lesser measures have brought about cure. In all these abdominal cases which can be grouped under no short title but which present symptoms suggesting trouble now in one region, now in another, it should not be the practice to approach and expose simply the part where the trouble is thought most likely to be, but by a wide incision to investigate the whole of the abdominal contents and to recognize and as far as possible to remedy the various abnormalities. As regards end results, while great improvement may be expected, a perfect condition of health is not necessarily attained.

3. **An Operation for Movable Kidney.**—G. S. Thompson describes a new operation for movable kidney the principle of which consists in the insertion of the kidney into and its suspension by a sling and the fixation of the latter to the posterior abdominal wall. The sling consists of a net made from chromicized catgut or preferably floss silk. The netting by its presence provokes a celluloplastic exudation which surrounds and infiltrates the meshwork and in time forms by organization a firm adventitious tissue capsule in addition to the extraneous capsule already present.

5. **Tetanus Treated by Injections of Carbolic Acid.**—P. Stewart and J. T. C. Laing report the case of an English officer who manifested the symptoms of tet-

anus seven days after the receipt of several shell wounds. Despite the use of repeated and large doses of tetanus antitoxin and of full doses of chloral and bromides the condition grew steadily worse. At this stage it was decided to commence treatment by means of carbolic acid. Accordingly 2 c.c. of a 5 per cent. solution were injected hypodermically into the abdominal wall every two hours. Improvement commenced on the same day; the tetanic spasms diminished in frequency, and the patient was completely cured one month after the first signs of tetanus appeared.

Berliner klinische Wochenschrift.

November 30, 1914.

War Neurology.—Oppenheim states that neurological ailments furnish an enormous contingent in war morbidity. At the very beginning of the war the author obtained permission to open neurological wards in a public museum. The beds were soon filled with 100 sufferers. Thus far it is too soon for complete reports, but certain types of affections may easily be isolated. Neuroses and psychoses are very common, especially the physico-psychic trauma. Overexertion, hardships, mental excitement due to the horrors and cruelty of warfare! — our chief surprise is that psychoneuroses are not much more frequent than they actually are. The author has found that the psychoneuroses almost always occur in the predisposed. Patients with hysterioneurasthenia, neurasthenia, psychasthenia, were by their own admission neuro- and psychopaths and generally recognized as such long before the war. A few had been injured by chronic alcohol consumption, and others, mostly officers, had suffered in the past from concussion of the brain. Of cases with sound *anlage* the author recalls some in which the first explosion of a shell close by caused an exogenous neurasthenia. There are no essential differences between war and peace neuroses. In war, dreams have very largely a content of war scenes. One even who takes his nap at noon may reenact the scenes of battle in his dreams and the author recalls a case under these conditions of somnambulism or sleep drunkenness. Cardiovascular disturbances often accompany these emotional affections and as a result various vasomotor complexes are seen. The sound of heavy projectiles as they pass the ear, or the nearby bursting of shells cause states which bear some resemblance to lightning stroke, in that both functional and organic lesions may result. In certain mild cases of epilepsy warfare may increase the number of the attacks. To what extent heat stroke may act in this connection we do not at present know. A case of Graves' disease seems to have developed under extraordinary privation and overexertion. Of quite another class are the organic diseases due to injuries of the head and spine. These are not of common occurrence and may be passed over here as may also the lesions of nerves and plexuses. In certain cases, however, we see intense neuritic pains associated with psychoneurotic and vasomotor disturbances. The pains cause attacks of mania, in the midst of excitement and confusion. There is a marked periodicity and in the intervals the patient is quiet with mind clear. These attacks of pain seem to depend on exogenous causes, for they are precipitated by the slightest noises and the patients may require complete isolation. A careful analysis of all the symptoms shows that these cases have their analogues in traumatic psychoneurosis after railway accidents. The author gives much space to the discussion of this affection.

Injuries a Frigore in War.—Melchior discusses this subject with special reference to the winter campaign on the Eastern frontier. In several wars of the last century the number of troops placed hors du combat from cold injuries was in the vicinity of 2 per cent. Actual freezing of the tissues is not implied, for the latter are only cooled to a certain point and the cooling must be long continued and as a rule be due to dampness. Prolonged moisture seems more deadly than dry cold ice contact. "Moisture gangrene" is in fact a term often used for these lesions. In dry cold weather, aside from foot lesions, we see frostbites of the fingers, nose, ears, and penis. Individual predisposition to these injuries in war is very variable. In times of peace we see certain classes suffer, as the anemic and alcoholic. In warfare we have to add the coincidence of certain constitutional diseases which greatly involve the nutrition—typhoid, scurvy, dysentery and cholera. One author has ascribed gangrene in these cases chiefly as the parent disease rather than to the contributory cold. An important factor in producing these lesions is tight clothing, especially in overtight lacing of shoes and overgaiters.

Münchener medizinische Wochenschrift.

December 1, 1914

Tetanus.—This number of the *Wochenschrift* contains four more articles on this subject. Siemon finds the incidence of tetanus in his wounded to be 1.66 per cent. This figure is five-fold that of the warfare of the past century. As the morbidity of the French from this disease is "normal" (*i.e.* about one-third of one per cent.) the author suggests that the German figures must be due to a special factor. No tetanus spores were found in the German uniforms, and no explanation is at present available. Of the author's 26 cases the first ten were treated with serum and but one survived. Since then magnesium has been used invariably, in part without serum. Since October 1 all subjects have been subjected to a matured plan of treatment, and of 11 cases treated with serum, magnesium, etc., not one was lost. Nothing is said definitely of five other cases, which may still be under treatment. The remarkable "inversion of percentages" seen to exist between the first and second series (90 per cent. mortality and 100 per cent. recovery) must have been due in part to the systematic use of magnesium. Narcotics other than the latter were as good as absent in the treatment; a little chloral was given in the evening to secure sleep. Among other measures the hot bath and high noon solar radiation (artificial?) were practised. In twenty-eight hospitals under the direction of the author the latter's technique will be strictly carried out. Usener seeks to fix the precise indications for the exhibition of magnesium sulphate. Given subcutaneously it is indicated for the overexcitability of tetanus and is also a marked antispastic. It is therefore to be pushed in conditions which directly threaten life such as severe spasm of the oesophagus, tetanic dyspnea, etc. It should also lessen the number and severity of individual convulsions. Under a favorable nexus of conditions the drug when urgently indicated may be injected intradurally. Jacobsthal and Tamm believe that they can prevent infection of the system by radiating wounds with ultraviolet rays. Kromayer's lamp and the artificial high solar light may be used. Further, in a letter from Cologne, where so many wounded are interned, Professor Hochhaus is quoted in regard to 60 cases of tetanus received from the front, in which serum treatment was said to have been much inferior in results to the magnesium and Baccelli treatment. Martin had 5 recoveries in 8 cases (treatment chiefly magnesium). Geuer had 6

recoveries in 10 cases, treated chiefly with serum. Wette on the other hand had but 3 recoveries in 13 cases. Other small series were reported with variable results under a plethora of remedies of all kinds. These small series came from various scattered hospitals. Only one thing is certain, that despite the high mortality of some individual series, the old wholesale mortality of 80 to 90 per cent. no longer exists. To give serum rightly, as a parallel to animal experiment, it should be injected by the quart, a possibility quite impracticable. Nevertheless its use has been a marked factor in reducing mortality.

Puerperal Infection with Fraenkel's Gas Bacillus.—Schüler seeks to describe the disease picture due to puerperal infection with the *Bacillus aerogenes capsulatus*. Of special interest is a case of "eclampsia" complicated with puerperal infection. While sewing, a woman who should have been about four months pregnant fell from her chair in convulsions and was admitted unconscious into the clinic. The urine was quite normal. Blood serum hemolytic. Fetus expelled spontaneously, but placenta could not be delivered save by manual extraction. It was found to be a so-called hemolytic placenta. From the blood a pure culture of Fraenkel's bacillus was cultivated. The woman never recovered consciousness, dying about 9 hours after admission. At autopsy there was sufficient evidence of a general and local infection with a gas bacillus. The problem is then to show whether or not eclampsia had ever existed. This must be answered in the negative. There were metastases of infection in the cerebrum to account for the convulsions of cholemia or nephritis—there was no evidence at all. One might of course style the affliction clinical eclampsia—puerperal eclampsia even. But it is evident that such a designation is purely symptomatic and could be so stretched as to indicate a variety of conditions. One thing asserts itself persistently, to wit: some cases of socalled "toxemia of pregnancy" could be brought within the compass suggested by this observation. Some authorities have suggested that puerperal sepsis will be found to depend largely on previous toxemia of pregnancy. In all alleged cases of toxemia of pregnancy, when hepatitis or nephritis is absent, and perhaps even when present, the systemic blood, placenta, etc., should be tested for evidences of gas bacillus infection.

Deutsche medizinische Wochenschrift.

December 3, 1914.

Dysenteriform Affections.—Leschke states that a military surgeon can hardly do otherwise than to regard every diarrhea with bloody and mucoid stools as dysentery. In the majority of these cases bacteriological study confirms the diagnosis; but there occurs a typical clinical dysentery in which none of the dysentery bacilli are to be found. Such cases are usually benign and it is highly important that they be separated from the true dysenterics. The pseudo cases simply represent any diarrhea in which blood and mucus may chance to appear in the stools from causes in no wise connected with dysentery. Of the various conditions under which in theory such cases can develop, no one has as yet been shown to predominate strongly. Of a number of cases cited by the author, one appeared to be an enteritis due perhaps to parasites, another represented the results of food poisoning, a third may have been due to parenteral infection or an infectious metastasis, a fourth may have been an example of anaphylactic enteritis, etc. A strong predisposition appears in the lymphatic constitution. Pseudodysentery ought to heal in a few days under simple hygienic measures, which include rest in bed. Inwardly it may be necessary to combat the presence of a toxic or irritating substance in the bowel, and the author gives animal charcoal in large doses. As to a preliminary dose of castor oil in such cases the author makes no mention. Semi-solid food is given until all diarrhea ceases.

Treatment of Tetanus Solely with Magnesium Sulphate.—Syring reports a single case of tetanus in which no serum was given. The incubation period was twenty days and the case was correspondingly mild, the chief symptoms mentioned being trismus and local spasms in the infected and opposite arm. The mild course might well be attributed in part to the prompt and vigorous use of the magnesium. Patient was ill but eight days, and during this period he received 25 injections of 10 c.c. each of a 10 per cent. solution. The mode was doubtless intramuscular throughout, but nothing is said of it. Indeed, from the careless use of the language one might receive the impression that the remedy was given *per os*. So striking a fact should surely have been emphasized decisively. Dyspnea developed on the fourth day of treatment and calcium chlorate was twice injected. It was on this day that the magnesium first showed control of the disease. The dose was now markedly decreased and improvement became steady. The author at the close of his very brief article states that the magnesium was tolerated "without reaction," which seems somewhat to antagonize his account of injecting calcium as a result of dyspnea. It is therefore likely that he regards the dyspnea as simply marking the limits of tolerance.

Dangers from the Use of Histamin.—According to Sieburg the protein cleavage product known as histamin (literally B-imidoazolethylamin) is now suitable for medical usage. It has been studied extensively in animal experiment, and is known to be a severe poison. It causes uterine contractions, bronchial spasms which may cause death, and other severe phenomena. Tested on women in labor in 6-8 mgm. doses it caused marked contractions of the uterus, but also so many untoward symptoms (headache, palpitation, vomiting, rash, etc.) that its use as an oxytocic is not to be thought of seriously. It may of course be possible to combine it with correctives, with or without true synthesis. It may not be known to all our readers that B-imidoazolethylamin is a natural constituent of the secale cornutum and some of the oxytocic action of the latter is evidently due to the subject under consideration. Substances closely related, if not identical with it, are known to appear in the body at times when they seem to be the part cause of anaphylaxis. Some authors regard the substance as only potentially toxic, the toxicity being elicited by concentration differences between the substance and medium.

The Meningeal Reactions in Scarlet Fever.—P. Mauriac and P. Philip state that Hutinel has recently called attention to the meningeal reactions frequently accompanying uremia. The complexity of this subject is further increased by the fact that during scarlet fever there may be various types of meningeal involvement. These types may be associated with aural, nasal, or uremic complications, or there may be simple meningeal reactions without the existence of any true meningitis. If during the eruptive or convalescent periods of scarlet fever uremia develops, the meningeal symptoms may readily be explained on the basis of the nitrogen retention. If, however, in such a case, convulsions suddenly arise in association with a high temperature and other signs of meningeal irritation, one is justified in thinking of an acute infection of the meninges superadded on the meningeal intoxication. In one of the authors' cases a pneumococcic meningitis was grafted on a simple uremic irritation of the meninges.—*Journal de Médecine de Bordeaux*.

Insurance Medicine.

The Importance of Examination of the Mouth and Teeth from a Life Insurance Standpoint.—Dr. George V. I. Brown says that the very strong point in favor of some form of mouth examination, and particularly from a life insurance standpoint, is that often it is not the neglected mouths, even though the teeth be uncleanly and full of cavities, that are so likely to harbor sinister possibilities, as the mouths of persons of wealth who have all their lives paid for the highest and best dental service, and whose mouths are quite commonly shining evidences of the skillful manipulative abilities of their dentist. The reason, after all, is quite simple. Teeth receiving little or no care as to their preservation are removed when through pain or swelling they offend; whereas the misguided efforts of the conscientious, high-class dentist whose code of practice demands that every effort shall be made to save every tooth only succeed in masking the trouble. Under artificial tooth crowns and bridges and above and below roots of teeth that have been treated for long periods there exist to-day almost everywhere bone cysts or other pus formations. These assume a much more serious rôle than is usually appreciated. These are the factors it is difficult to uncover, and they exist where least looked for. Naturally it is among individuals of this class that one would expect to find applicants for large amounts of insurance. Chronically inflamed gums, or pyorrhea pockets, or loose teeth indicate almost invariably a tendency to indicanuria. Often diabetes and other similar affections accompany the same symptoms. Infections from these sources, in addition to the ill effects upon the gastrointestinal tract of the constant swallowing of the pus microorganisms may also cause Ludwig's angina or edema of the glottis with fatal results, and may be indirectly accountable for septicemia or pyemia. One of the earliest symptoms of acute leukemia is sloughing of the gums about the necks of the teeth. There are certain mouth infections which are almost invariably fatal. Whether because of increased virulence acquired by the organism, or because of weakened resistance of the individual, due to other disorders, it is difficult to say with accuracy. Malposed teeth, with the aid of the *x*-ray, are found in the mouths of many people who never previously suspected their existence. They are frequent causes of nervous disturbance, particularly neuralgic pain, and have been found at the site of beginning sarcoma and carcinoma. An unaccounted for tooth may, therefore, be considered a menace. Malposed, impacted third molars have been responsible for many deaths. Discolored teeth without cavities, or with roots which have been improperly filled, and perhaps with a history of previous serious suppurative processes in their treatment, are most important from a life insurance standpoint. Teeth that have large carious cavities or diseased roots which discharge through fistulæ upon the gum surface are easily discovered, but seldom dangerous. The most serious results come from teeth giving no outward evidence of being affected by any unusual condition except a more or less dark appearance when compared with adjoining teeth. Upon inquiry there can usually be elicited a history of a fall or some traumatic injury which has happened years before, yet was sufficient to injure the little nerve filaments that form the connection between the tooth pulp and the main nerve at the apical end of the root. This devitalized pulp may supply a more or less constant infection which is forced up through the apical end of the root by the gases formed within the pulp chamber, and is doubly dangerous because of the likelihood of direct absorption into the general system or distribution through the bone circulation. Teeth of this character are much more common than is generally supposed, and give greater, far-reaching pathologic effects than easily diagnosed, serious looking tooth conditions. The tongue as an index of disturbed intestinal and general conditions has long been recognized. A person suffering from cancer of the tongue in its early stages could successfully pass an examination for life insurance unless the mouth were examined. Leukoplakia is so often a precursor of cancer, and so frequently found in leutic cases, while other evidences of syphilis and also of tuberculosis may be noted in the region of the mouth, and particularly the tongue; and there may be no other marked outward symptoms of these affections, so that the report of such a tongue surface would certainly warrant a more than ordinarily careful examination of the individual. A complete picture of the actual physical condition of an applicant with regard to his life prospects cannot be prepared without at least a cursory examination of the mouth and its immediately associated anatomical parts. The following questions might be included in a regular form of examination blank: (1) Describe the general appearance of the teeth, mucous membrane of the mouth and pharynx. (2) Does the mouth contain the full number of teeth, according to the age of the individual? (3) Are there any discolored teeth in the mouth? (4) Is there an irregular, contracted upper dental arch with a high, narrow palatal vault? (5) What is the general appearance of the tongue? The replies would enable the central examiner to decide whether there was any reasonable ground for suspicion of the existence of any condition which might become a serious menace to life. If a doubt should exist the Röntgen ray, electrical mouth lamps for transillumination and other modern methods of determining actual conditions would make the findings as complete and definite as possible. In many instances the disadvantageous conditions could be promptly corrected, thus converting an unfavorable risk into a good one.—Medical Section, American Life Convention.

Presumption of Examining Physician's Good Faith.—It is held that an association which has insured a person, after a medical examination, cannot attack the statements of its physician in an action on such policy, and it will be presumed that the physician acted in good faith and in the full discharge of his duties when he made the examination and report.—Wyman v. Manufacturers & Merchants' Life Assn., 182 Ill. App. 511.

Warranty — Receipt of Medical Advice.—A breach of warranty that the insured has not had medical advice during the last five years will render void a contract of life insurance conditioned thereon. The burden of proof is on the insurer to show untrue the insured's warranty in this respect.—National Union v. Kelley, Oklahoma Supreme Court, 140 Pac. 1157.

Book Reviews.

THE LIFE AND LETTERS OF NATHAN SMITH, M.B., M.D. By EMILY A. SMITH. With an introduction by WILLIAM H. WELCH, M.D., LL.D. Price $2.50 net. New Haven: Yale University Press; London: Humphrey Milford, Oxford University Press, 1914.

No medical man in America has better deserved that his memory should be kept green than Nathan Smith. He was probably the greatest factor in the advance of medical education this country has ever known. He was concerned in the foundation of several New England medical schools and actually founded the medical school of Dartmouth, New Hampshire, and that of the University of Vermont. Nathan Smith's ancestors came from Norfolk, England. His letters comprise the greater part of the book and provide fascinating reading. In them are depicted the earnestness and thirst for knowledge of the man. The editor of the work is to be sincerely thanked for having given to the world an intimate sketch of one of the greatest of American medical educators.

THE SCIENCE AND PRACTICE OF DENTAL SURGERY. Edited by NORMAN G. BENNETT, M.A., M.B., B.C. (Cantab.), L.D.S. (Eng.) Dental Surgeon to St. George's Hospital and the Royal Dental Hospital, London; Member of the Board of Examiners in Dental Surgery, Royal College of Surgeons of England. With an appendix on Dental Jurisprudence by P. B. HENDERSON, B.A. (Oxon). With nine hundred and ninety-three illustrations. Price $9.00 net. New York: William Wood & Co., 1914.

THIS one volume cyclopedia of dentistry, with its forty-four subjects covered by thirty-five distinguished British dentists, is a somewhat venturesome undertaking, but one which has succeeded remarkably well. The risk lay in the selection of matter which could best be spared to make a one-volume work, and one of a size not too bulky for easy handling. The editor has omitted all the old prosthetic dentistry—plate teeth and entire dentures—and private laboratory activities no longer demand the attention which they once enjoyed. Again the historical method of developing subjects has been abandoned and the only literature quoted is of relatively recent origin. In the interest of further concentration the editor has succeeded brilliantly in making theory and practice go hand in hand throughout the work, thus saving a vast amount of duplication. We cannot refrain from citing a couple of instances which illustrate this point. The work begins straightway with the development of the teeth, this subject leading promptly to abnormities of development and implantation. Before we realize it we are in the midst of orthodontia, with its numerous springs and braces. Further, the editor having the belief that wisdom teeth are not entirely normal formations, we find the second chapter of the work devoted to the pathology and treatment of the third molars A little further on we come to the physiology and chemistry of the saliva, calculous deposit, and the technique for cleaning the teeth. The principles and practice of dentistry proper, orthodontia, caries, and pulp disease and filling, periodontitis, prosthesis (crown and bridge work) are discussed with extraordinary thoroughness. Of course, much that belongs under stomatology and oral surgery would be out of place in a work of this scope, which must necessarily omit borderland subjects. But progress in all science which bears directly upon dentistry is very fully considered—local anesthetics, dental radiography, dental electrotherapeutics, the bacteriology of the mouth, progress in juvenile dentistry, and dental jurisprudence.

HANDBOOK OF PHARMACOLOGY. By CHARLES WILSON GREENE, A.B., A.M., Ph.D., Professor of Physiology and Pharmacology, University of Missouri; Member American Association of Anatomists, American Physiological Society, Society of Pharmacology and Experimental Therapeutics; Fellow of the American Association for the Advancement of Science; Associate of the American Medical Association, etc., etc. With Seventy Illustrations, Including many new and in Colors. Price, $3.50. New York: William Wood & Company, 1914.

THIS new book on Pharmacology has much to recommend it. It is absolutely new, the arrangement of the subject matter is good, the chapters are short, and the author adheres strictly to his subject and does not wander into the neighboring fields of materia medica and therapeutics. As a rule each group or series of drugs is prefaced with a brief historical and chemical introduction; this is followed by an outline of the actions; these actions are then discussed in detail; and the chapter closes with a comparison of the drug with related drugs. The bibliographical references are brief but sufficient, and are particularly well selected. The dose table at the end of the volume is the least satisfactory part of the work. It gives the *average* dose and the *maximum* dose of the more important drugs, and a comparison of these doses shows some startling results; thus in some cases the average dose is the same as the maximum dose, and in some cases the maximum dose is less than the average dose. The book is well written and well printed, and should prove popular with students.

THE VACCINATION QUESTION IN THE LIGHT OF MODERN EXPERIENCE. An Appeal for Reconsideration. By C. KILLICK MILLARD, M.D., D.Sc., Medical Officer of Health for Leicester; Medical Superintendent of the Insolation Smallpox Hospitals, Leicester; Formerly Medical Officer of Health for Burton on Trent; Medical Superintendent of the Birmingham City Hospitals. Price, 6 shillings. London: H. K. Lewis, 1914.

THE author believes that there are two sides to the question of compulsory vaccination against smallpox and attempts to bridge over the great gulf that is fixed between the pro-vaccinist and the anti-vaccinist. He suggests that perhaps the whole truth does not lie with either side but will be found in an intermediate position lying somewhere between them. The book is valuable as a statistical study of smallpox in Great Britain in recent years. The author believes the situation at the present time is different from that at the time that infantile vaccination was made compulsory and that it is recent vaccinatin and not infantile vaccination that protects those exposed to smallpox. He gives interesting proof of the effect of vaccination in modifying smallpox and emphasizes the danger to the community of unrecognized cases of smallpox modified by vaccination. He prophesies that general vaccination will gradually be abandoned but that it will always continue to render invaluable service in protecting smallpox nurses and others especially exposed to the disease. This is the fairest and most consistent exposition of this subject that has come to our notice.

THE PROBLEM OF THE NATIONS—A Study in the Causes, Symptoms, and Effects of Sexual Disease, and the Education of the Individual Therein. By A. CORBETT-SMITH, M. A. (Oxon.); Barrister-at-Law; Captain (formerly R.F.A.); F.R.G.S.; "Officier de l'Instruc-Publique"; Editor of *The Journal of State Medicine;* Lecturer on Public Health Law at the Royal Institute of Public Health. Price $1.00 net. New York: Paul B. Hoeber, 1914.

THE proofs of this pamphlet on venereal diseases have been read by Prof. Sir Thomas Oliver. It purports to be a plain and straightforward account of such diseases and is intended for undergraduates at the English universities. A glossary of medical terms and a great amount of emotional fervor are included.

ATMOSPHERIC AIR IN RELATION TO TUBERCULOSIS. By GUY HINSDALE, A.M., M.D., Hot Springs, Va. Washington: Smithsonian Institution, 1914.

THE author of this interesting essay concludes that climate may be utilized as an adjuvant of great value for carrying out the hygienic dietetic treatment of all forms of tuberculosis and of many other diseases. Altitude *per se* has probably not any great influence. Florida and South Carolina in the winter, the Adirondacks in the winter as well as Arizona and New Mexico (except at 5,000, 6,000, and 7,000 feet) produce good results. The southern coast of California is as beneficial in the summer as in the winter. Redlands, Riverside, Monrovia or Altadena are all better than Los Angeles.

OESTERREICHISCHES BÄDERBUCH. Offizielles Handbuch der Bäder, Kurorte und Heilanstatten Oesterreichs. Verfasst und herausgegeben von Kais. Rat. Dr. KARL DIEM. Price 40 Mks. Berlin: Urban & Schwarzenberg; New York: Rebman Company, 1914.

THE 1914 official handbook of the Austrian baths contains an article on the chemical composition of mineral waters and their classification by Kofrat Prof. Dr. Ernst Ludwig; an article on the radioactivity of the healing springs and the technic of their use by Prof. Dr. Josef Tuma, and other similar discussions. There is an alphabetical list of the places and a map in the appendix.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 17, 1914.

DR. JOSEPH C. ROPER IN THE CHAIR.

Advertised Remedies for Cancer.—Prof. JAMES EWING considered the worthless remedies that were exploited by worthless persons who were without any standing in the profession, and the most worthless and most harmful person was the local quack. He knew nothing regarding the diagnosis of these cases, but pretended to be able to cure cancer, relying upon medication only. Such persons were found in almost every town in the country. The harm they did was by dealing with what they knew absolutely nothing about. But these people were not so serious from a commercial standpoint as were the institutional quacks. Then again there was an entirely different group of men who exploited the so-called curative remedies for cancer, members of the medical profession and in fairly good standing. This group of men belonged to an extremely dangerous class. They were injudicious and unethical, but they dealt with the more intelligent people. With regard to surgery, this was the great cure for cancer, but not in those cases where the disease had progressed far.

The Damage to Tuberculous Patients by Self-Administered Proprietary Remedies.—Dr. ALFRED MEYER presented this paper. He stated that the patient suffering from tuberculosis illustrated to a marked degree the truth of Pope's lines: "Hope springs eternal in the human breast." This psychological state and the long duration of the disease made him an easy prey for all who advertised their unholy wares. In a general way the objections to the self-administering of proprietary medicines by tuberculous patients were: First, such action presupposed the belief that each disease had a specific remedy. This belief was erroneous. Second, because logically, diagnosis comes first, and many of these patients treated their disease without a diagnosis by a physician. In a more special way the damage done was often because of the presence of large amounts of alcohol and opium in the supposed cure, and the false sense of improvement excited by the stimulant action of the one or the sedative influence of the other. Moreover, this self-treatment with nostrums bred a false sense of security and led to neglect of all the other valuable aids, which could only come from professional or institutional care and supervision. Perhaps the most serious handicap lay in the fact that tuberculosis was par excellence a disease in which early diagnosis and treatment were half the battle; hence, by deluding himself with a variety of cough medicines, tonics, and so on, the patient delayed his correct treatment, lessed his chances of recovery, and was relegated to the class of chronic, hopeless cases. The history of medicine from the days of Hippocrates, Celsus, and Aretæus, down to the present time, had with few modifications marked out the most hopeful course of treatment. Even if no direct harm were proven in an individual case from any particular advertised remedy, the lying statements in regard to most of them and the type of men responsible for others, would justify suspicion, antagonism, and public agitation against them. Fortunately for our multitudes of tuberculous and poverty-stricken people, this agitation had been carried on with increasing vigor for ten years, and during this time the American Medical Association, *Collier's Weekly*, and the *Journal of the Outdoor Life* had exposed many "cures" and many men. The author read a few of these exposures and said that this list of fraudulent advertisements, objectionable characters, and usurious profits from worthless remedies could be multiplied many times. An estimate made by the National Association for the Study and Prevention of Tuberculosis for the five years ending July, 1913, showed that five hundred fraudulent cures for consumption had been tried in the United States during that period, yielding a clear profit to the exploiters of $50,000,000. It was also estimated that $20,000,000 were invested in manufacture; that the annual income was $15,000,000; that one-third of the income was spent in advertising, leaving $10,000,000 a year of "blood money," taken from ignorant consumptives. In spite of laws, whether National, State, or municipal, the sordid work went on. Only a few days ago the speaker received a clipping from one of the great metropolitan journals, containing the announcement, in large letters: "TUBERCULOSIS CURABLE," and then, in smaller letters, the words "with new remedy which received the gold medal at the last International Medical Congress for Tuberculosis. Write for full information, etc." A pamphlet circulated from the address given mentioned London as the place of the last International Medical Congress. The tuberculosis Congress, however, was held at Rome in 1912, and no prize gold medal was awarded to any sort of remedy at the meeting of the British National Association in 1913, according to the published transactions. In controlling this great evil, so aptly called "The Great American Fraud," some check on cupidity would be realized from the various pure food and drug laws, but credulity, like the poor, "we will always have with us." The greatest help, in its reduction, in the author's judgment, might be anticipated by the education of the public, even that part of it which resented any attempt to "limit the freedom of eating what it might choose to eat and of taking such remedy as it might wish to take." This educational influence was being exerted steadily and effectively by the work of the National Tuberculosis Association, traveling tuberculosis exhibits, moving picture shows, educational leaflets, and, in this community, by the work of the Health Department, the public and private tuberculosis clinics, the Charity Organization Society, the State Charities Aid Association, the United Hebrews' Charities, the Association for Improving the Condition of the Poor, St. Vincent de Paul, and others. They should not neglect to emphasize the educational value of the many city and county sanatoria for tuberculosis, scattered throughout the State and country. The press of the country had also been of great value in spreading the educational campaign. About twenty-six bulletins annually, in regard to tuberculosis, are published in between eight and ten thousand newspapers, and it was figured that from three to five million readers were reached weekly by this publicity service. An investigation recently made by Dr. Meyer at the Bedford Sanitarium of the Montefiore Home led him to believe that this educational work was showing results. Less than half of the cases took proprietary medicines before admission and only in a relatively small number of cases were objectionable things used. In conclusion, let them say that they have not discovered a specific for tuberculosis, and they were honest enough to admit it. But with early recognition, hyperalimentation, hydrotherapy, and climatotherapy, regulation of the daily life down to the minutest detail, by controlling or removing a multitude of the complications which might arise in the course of the disease, they could arrest many of the cases and return multitudes to the wage earning class. Admission of his own limitations was the physician's first step in knowledge. Untruthful proclamation of the cures was the fakir's first step in developing a bank account.

The Evil for So-Called Cures for Narcotic and Drug Addictions.—Dr. ERNEST S. BISHOP presented this paper, which was read by Dr. Orrin S. Wightman. He said that when he was resident physician of the alcoholic and prison wards of Bellevue Hospital he first became aware of the existence of the many so-called cures for narcotic conditions which were supplied from a local office or by correspondence, and which were supposed to be carried out by the patient without further supervision, and he was surprised at the extent to which they had been patronized by the patients. So far as he had been able to learn these cures had been uniformly unsuccessful. Probably here and there would be found an exceptional case in which the patient was taken in the early stage of his addiction or was possessed of superhuman power to endure suffering, and through such a cure had escaped from his disease, but such a person was worthy of study as an unusual individual. As a result of careful inquiry into the experiences of various patients who had taken these cures, he had learned that the patient was furnished with a number of bottles of medicine to be taken in sequence, and in the dosage indicated. At first there was no discomfort. There might be even an effect of overdosage of the drug from which the patient sought escape. As the treatment proceeded, however, the patient got to a point where he experienced the discomfort and symptomatology of insufficient supply of the narcotic drug. He adhered to the schedule as long as was humanly possible and then adopted the simple expedient of increasing the dosage for relief. He might attempt this several times, but in the end found

it impossible and gave up the struggle. He had never had any of these cures analyzed, but there was no doubt in his mind as to their principal content. It was the drug of the patient's addiction in diminishing doses, and whatever other drugs were present their effect was negligible. These "cures" were therefore nothing but unscientific and unsupervised administration of the timeworn method of gradual reduction. It was almost certain to fail without constant watching and control. The sanatoria where it was practised demanded for its carrying out months of residence, close supervision, observation, and restraint, and the attendance of a skilled physician with experience in this work. Even under the best conditions there would be months of nagging, nerve wearing, suffering through a slow convalescence and readjustment, and even then a high percentage of relapses. It had been, however, in the state of previous ignorance of the disease, the only fairly efficacious method in general use. An interesting sidelight on these "cures" and on the character of the remedies they dispensed came from the frequent statements of patients that they purchased these remedies not with any hope of cure or belief in their efficacy, but to obtain the opiates, without which they could not exist. He had been told that this practice had increased since the passage of the Boylan law. The men using these cures were usually not the well-to-do, but those compelled to stay at home and continue their work and who had but a small amount of money at one time. There was no relief for these individuals at the charity hospitals and they could not afford the more expensive sanatoria. The evil results of these cures were that the sufferers would have expended their money which they could ill afford and would have added despair to previous discouragement. A second class were not so desperately harmed; they had simply secured in the way that seemed most available and least dangerous the drug upon which they depended. The dealers in these so-called "cures" were simply furnishing opiates at extortionate prices. Perhaps they could point to cures and bring some of them in to support their procedure, but every method from Christian Science up could do this. The sufferers should be protected from these dangers, but the question was how to do it. The method was by investigation and legislation and the main and most reliable help should come from the medical profession. There should be some means of instructing the public along legitimate lines concerning narcotic drug use and its remedy. The stigma of mental and moral weakness should be removed and the case presented as that of a definite disease condition. The sufferer should be warned that it was better for him to use his drug in moderation until he could obtain adequate relief than to attempt unvouched for methods, that inefficient treatment was worse than no treatment at all. There should be means provided for the victim to procure sufficient of his narcotic to enable him to live until he could take adequate treatment and he should be instructed in a few simple facts which would enable him to continue its use with least harm until such time arrived. Narcotic drug disease was and would before long be recognized as one of the most definite clinical conditions in its fundamentals, basically a clean-cut disease condition. The obstacle was that they had studied complications of autotoxemia and anxiety psychoses instead of intrinsic narcotic effect, and labeled the patients as mentally diseased and degenerate. This obstacle must be removed and unbiased, competent clinical study substituted. A committee should be appointed connected with their medical organization or with the Board of Health for searching out and disseminating real facts. Hitherto the public had received its information on this subject from laymen, but it was a medical problem of great importance and the instruction should come through duly established medical and health organizations.

A Survey of the Proprietary Remedy Question.—Dr. W. A. Bastedo read this paper. He said he would not discuss the relation of proprietary remedies to the patient, the physician, the retailer, the wholesaler, the manufacturer, the advertising agent, or the one who published the advertisements, though he stated that each was important, for the patent-medicine business was a large one, paid well, and represented immense vested interests. Nor would he stop to discuss the statement that the people of the United States were the largest drug consumers on earth, using more drugs per capita than any other nation; but would proceed to speak of the proprietary remedies themselves. It must be recognized at the outset that proprietary rights were not of necessity wrong rights. As instances of simple chemical drugs which had been proprietary the writer mentioned acetanilid under the name of antifebrine; acetphenetidine, under the name of phenacetine; theobromine sodiosalicylate, under the name of diuretin. In the countries in which these drugs were manufactured, where patents might be granted for processes of manufacture but not for the chemical itself, the drugs were sold with only the usual profit to the manufacturer; but through the laws of the United States the patents granted for them not only forbade that any but the proprietor should manufacture such chemicals by any process whatever but even went to the length of forbidding that any but the proprietor should import them or place them upon the American market. For those remedies, however, the patent had expired, and if physicians would prescribe them under their chemical names the price would be much less to the patient. Of the galenical that bore its formula on the label little was to be said. What was needed here was such regulation as would prevent the placing of untruths upon the label or in advertisements. Of the galenicals with secret formulas, the cancer cures, the consumption cures, and the drug-habit cures had been reviewed, but the field was large indeed. If the question was asked whether there was anything fraudulent in the secret nostrum business, and, if there was, whether the proprietors knew about it, one had only to observe the change in labels when the Food and Drugs Act was passed. To emphasize the harmful effect of self-medication Dr. Bastedo called attention to some of the preparations whose chief ingredients were alcohol, cocaine, morphine, or acetanilide. According to statistics collected by the Department of Agriculture there were in the United States 911 cases of acetanilide poisoning, with thirty deaths, in the year 1909. Another way in which the unwary were captured was through the "beauty hints" and "health hints" in the newspapers. Even some of the metropolitan papers lent themselves to this reprehensible practice. The manufacturers were not alone responsible for the harm that their preparations did. The layman had been shown the facts over and over again and the physician had not been without responsibility in the distribution of the secret nostrum. In concluding, Dr. Bastedo said he had attempted to show that proprietary rights in medicines might be used for the exploitation of the public; that in spite of many honest manufacturers the proprietary secret formula was the one that especially lent itself to fraud of the worst possible kind, since it dealt with human life and health, and to emphasize his belief that a law which in addition to forbidding untrue statements in advertisements and on the label also forbade secrecy in the formula would prove to be greatly in the interest of the public health.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 24, 1914.

Dr. Asa B. Davis in the Chair.

A Preliminary Report of a New Method of Painless Childbirth.—Dr. Alfred M. Hellman presented this communication. He referred briefly to the various efforts that had been made to attain a painless childbirth and stated that on July 21, 1914, Professor Ribemont Dessaignes of the French Academy of Medicine delivered before that body a lengthy address on this subject. In 112 labors he had used a drug obtained by the action of hydrochloride of morphine on living ferments resembling beer leaven. By this special method of treatment the toxicity of opium became about one-fifteenth that of morphine and the entire morphine was transformed into a substance that crystallized in the regular way. Professor Ponchet, who further examined the drug, said it resembled the oxydimorphine of Marne. This agent made the organism more susceptible to such drugs as strychnine and digitalis, accentuated the vasomotor reflexes, exaggerated the general reflexes, and increased salivary, intestinal, and renal secretions. Toxic doses were reached only when two or three centigrams were injected for each kilogram of body weight, and were evidenced by bloody and mucous diarrhea. The first toxic cerebral symptoms resembled inebriation. Professor Dessaignes found that the drug acted on the brain and sympathetic centers without noticeable effect on the spinal cord. It was probably carried there by the blood stream. Its action was most prompt; a pricking sensation was felt within two or three minutes. The patient became drowsy after ten to twenty minutes, and

there was no further sensation of pain. Professor Dessaignes had obtained complete analgesia in 84 cases, marked but not complete analgesia in 24, and four claimed that they had no relief, but their cries became less violent. The analgesia lasted from thirty minutes to twelve hours. In 63 cases but one injection was used; nine patients received three, and one, five injections. There was no effect on the uterine contractions as tested by the hysterograph of Professor Fabre of Lyons. There was one case of postoperative hemorrhage. The placenta came away on an average thirty-two minutes after birth. There was no mental anxiety, no physical exhaustion, no disturbance of temperature or pulse, and no after pains until the analgesia had worn off. The involution was normal and nursing was not affected. The result of 112 labors was 115 babies, of whom 77 cried out at once, 28 seemed dazed, and were oligpneic, but after a few minutes breathed with perfect freedom and were comparable to cesarean babies. There was one fetal death where the fetus was doing poorly at the time the mother was admitted to the hospital. Two babies had convulsions shortly after birth, the autopsy showing meningeal hemorrhage. Three premature children died at the end of one, two, and eleven days after birth; all the others left the hospital in perfect health. The drug was given hypodermically, 1.5 c.c. for the first dose and 0.5 c.c. for succeeding doses. Dr. Hellman said this report had encouraged him to try this drug, but owing to the failure of a promised shipment from Paris he had but three cases to report in which it was used by the house gynecologist at the Lebanon Hospital. These were three normal primiparæ and the administration of the drug was commenced when the pains were about five minutes apart and the os dilated two fingers in the first and third cases and four in the second. Pain ceased in from fifteen to thirty minutes after the first injection of the drug. A second injection was given in each of the cases, and in each instance one c.c. pituitrin was given when the head was on the perineum. While the cases were too few to warrant the drawing of any real conclusions, the author said that the drug certainly relieved the pain of labor and caused a certain amount of amnesia. It would probably be found to lengthen the second stage of labor. It was harmless to mother and child and had no effect on the puerperium. There would be a certain number of babies born oligpneic. He did not know whether this would be serious enough to discredit the use of the drug or not. It must, in order to be proved safe, allow the woman to deliver herself without the addition of another poison, pituitrin, in any appreciable number of cases. The work was sufficiently encouraging to warrant further experimentation.

The Physiology and Pharmacology of the Excised Human Uterus.—Dr. CHARLES LIEB read this paper. He said he had recently demonstrated the pharmacodynamics of some ecbolic drugs on the isolated uterus of the guinea pig and drew some broad conclusions as to the action of these drugs on the human uterus. Objections were raised based on the physical differences between the human uterus and that of the guinea pig, and this had led him to investigate the physiology and pharmacology of the surviving human uterus and tubes. He first discussed the results reported by those who had studied the movements of the human uterus *in situ*, and then described his method of investigating the movements of excised segments of the human uterus and tubes. As soon as the organs had been excised segments were cut from them and transferred to a large jar of oxygenated Ringer's solution. If the segment was to be studied immediately the temperature of the solution was maintained at 38° C.; if the tissues were to be preserved for later experiments the solution was kept at 5° C. to 10° C. and placed in the ice-box. At least once in twenty-four hours the tissues were transferred to freshly prepared oxygenated Ringer's solution. Such treatment was not deleterious to contractile tissue as had been shown by Gunn for the heart and Herz for the intestine. The author had preserved guinea-pig uteri for 196 hours at such low temperatures and then when suspended in warm Ringer's fluid the movements were found to be identical in type with those made by the segment after its removal from the body of the animal. Nearly all the experiments were carried out on the longitudinally disposed outer layer, the segments being taken from the anterior surface of the uterus near the fundus. The presence of two well-defined layers of smooth muscle in the tubes made it possible to study the longitudinal as well as the circular fibers. The movements of the muscle were recorded by a lever of the first order on the smoked paper of a slowly turning kymograph. The author then illustrated the results of his experiments with charts. In the non-pregnant uterus the contractions of the external coat were slow but powerful. There was a considerable variation in the completeness of the individual contractions as well as in the extent of the relaxation. The movements might be regular in their rhythm or the intervals between successive contractions might differ greatly. Usually the contraction was followed promptly by relaxation, but sometimes the fibers remained contracted for a considerable period. In some tracings the rate of the movements was very slow. This was due to the long pause which intervened between successive cycles. The external longitudinal coat contracted at the rate of 10 to 60 times per hour. The development of the movements was interesting when the experiment was set up. There was a progressive loss of tonus from 20 to 60 minutes and then quite suddenly there was an enormous increase in the tonus and spontaneous contractions made their first appearance or they became larger than they were during the stage of low tonus. The contractions having once begun continued for hours with little change in rate or strength. The level of tonus was subject to considerable variation, the exact explanation of which was not at hand. In the parturient uterus the movements of the external longitudinal coat were of two types. In the first they were simple waves. The contractions usually began and ended slowly. In this type there was but little change in tonus. In the second type there were large coarse waves on which were superimposed smaller contractions. The rate of the small contractions was subject to considerable variation, but it was probably not far from 60 to 75 per hour. In one case in which the movements of the oblique fibers were recorded the waves corresponded to type one. In studying the movements of the Fallopian tubes, he found that in the non-pregnant state the longitudinal fibers had a much faster rate of contraction than those of the body of the uterus. In the non-pregnant tubes the rate had been found to vary between 120 and 200 per hour. The contractions were usually small, the height varying inversely as the rate. They might be quite regular in rhythm and strength. Occasionally there was an ill-defined tonus wave on which the small contractions were superimposed. The movements of the inner layer of muscle resembled closely that of the outer layer. In the parturient tubes the contractions assumed a new character. The movements of both the circular and the longitudinal fibers became slower but much stronger. The tonus changes became very pronounced. Usually the ascending limb of the curve was smooth and unbroken, but the descending limb was interrupted by numerous small contractions, not infrequently following one another without marked pause, while occasionally these small contractions were separated by strikingly long periods of inactivity during which the tube remained in decided relaxation.

Dr. Lieb then discussed the origin of uterine movements and stated that inasmuch as the movements were not due to impulses derived from the central nervous system nor from the adjoining nerve plexuses, they must originate in the organ itself. They might be due to an inherent rhythmic function of the muscle cells themselves, or they might be the result of impulses formed in the nerve cells found within the walls of the tubes and uterus. Each of these views had its supporters. The absence of a well-defined nerve plexus, corresponding to Auerbach's plexus, in the wall of the intestine, led him to believe that the stimuli arose within the muscle fibers. The writer then described and illustrated by charts the action of some of the ecbolic drugs on the excised human uterus. With the addition of suprarenal extract sufficient to make a 1-2,000,000 solution, the uterus at once contracted powerfully and there was a great increase in the rate of movements. The tonus was markedly increased. These effects were of comparatively short duration, probably because of the conversion of the suprarenal extract into a less active oxidation product. From these experiments the conclusion was probably justified that the sympathetic innervation of the human uterus was always motor in quality. The beneficial effects of a suprarenal extract douche could now be explained. In addition to the constriction of the bleeding vessels, suprarenal extract produced a contraction of the uterus itself. Thus the flow of blood to the ruptured vessels was diminished and the hemorrhage stopped. The effect on the uterine muscle was probably at least

as important as that on the vessels. The question arose, could postpartum hemorrhage be controlled by the systemic administration of suprarenal extract? It probably could not.

When the drug was administered by mouth, subcutaneously or intramuscularly, the absorption was so slow and oxidation at the point of application so rapid that but little of the drug entered the circulation. The intravenous administration would undeniably produce a marked stimulation of the uterus, but the sudden rise in blood pressure and the redistribution of the blood would more than counterbalance this effect and the hemorrhage would be increased. Suprarenal extract should not be used as an ecbolic. The intravenous administration would probably be dangerous and the other methods of administering it would be worthless. Dr. Lieb then outlined his experiments with ergotoxin, parahydroxyphenylethylamine, one of the amines present in ergot and closely related to suprarenal extract, imidoazolylethylamine, a third active constituent of ergot, and the fluid extract of ergot. The effect of the latter drug on the isolated uterus was on the whole distinctly disappointing. A number of different samples had been tried, usually after distilling off the alcohol and replacing it with Ringer's solution. This was necessary because the addition of alcohol to the isolated uterus resulted in more or less marked depression. There occurred a very slight increase in tonus, but a considerable augmentation of the rate and strength of the individual movements. An artificial fluid extract had a similar but more striking effect. The author finally described his experiments with pituitary extract. He found its effect on the non-pregnant uterus or tubes surprising. Small doses usually had no effect; large doses, such as produced marked stimulation of the pregnant uterus, might cause a definite depression or they might not influence the movements at all. It had been suggested that beta-imidoazolylethylamine was the active constituent of pituitary extract. It was evident from his experiments that such was not the case. The non-pregnant and parturient uterus reacted very differently to pituitary. The non-pregnant uterus was unaffected or depressed; the parturient uterus was stimulated. The simplest explanation of this was that the human organ, like that of the cat, changed its innervation, or, rather, during pregnancy, its motor innervation became predominant. Such, however, was not the case, for epinephrine produced stimulation of the human uterus whether it was pregnant or not, nor did the parturient organ appear to be more sensitive to epinephrine. The only explanation was that some substance sensitized the uterus to pituitary. What this substance was Dr. Lieb did not know, but it was not epinephrine. From his experiments it seemed that the uterus might become sensititzed to pituitary as early as six weeks after conception. It was true that during pregnancy the pituitary gland hypertrophied and that after the expulsion of the fetus retrograde changes occurred. The hypertrophy was limited to the true glandular lobes, the anterior and middle divisions. The posterior lobe showed no increase in activity. But it was from the posterior lobe alone that the ecbolic principle could be obtained. This indicated that the posterior lobe was not concerned with normal labor; it was not necessary to life. Oddly enough extracts of this lobe had not been shown to have a demonstrable pharmacological activity. But this was the lobe that hypertrophied during pregnancy. It was apparent that if the pituitary gland was to be regarded as intimately concerned with the onset of labor, Dr. Lieb said, the hormone should be sought not in the posterior lobe but in the anterior portion of the gland.

Dr. JOHN O. POLAK said that such a paper as that presented by Dr. Lieb should not go without some discussion. It was a very valuable contribution in correcting erroneous conceptions of the action of drugs. He had been particularly impressed by the diagram showing the effect of pituitary extract on the uterine muscle and he could not see why, if that showed the physiological action, they should continue to use it to check hemorrhage. Professor Fabre of Lyons had done some work along these lines in the study of the effect of certain drugs on uterine contractions in the pregnant state which was very similar to this. It was very interesting to see the force, and especially the very high force, of the contraction. Such work could not help being of the greatest advantage; it gave much valuable information and pointed the way to a more intelligent use of drugs in the treatment of pathological uterine conditions.

SECTION ON SURGERY.

Stated Meeting, Held December 4, 1914.

DR. CLARENCE A. MCWILLIAMS IN THE CHAIR.

Gangrene of Gall-Bladder from Twisted Cystic Duct.—Dr. WALTER C. CRAMP presented this patient, a man who had been admitted to Bellevue Hospital suffering from pain in the abdomen, nausea, and vomiting. From the history it was supposed that his trouble was due to indiscretion in diet and he was placed in the medical division. A tentative diagnosis of gastritis was made. The following day he was transferred to the surgical division. There was rigidity over the right upper quadrant, a temperature of 99° F. but no symptoms indicative of obstruction. There was a high leucocyte and polymorphonuclear count, and an epigastric tumor. Immediately, on making the incision, the gall bladder protruded through the opening. It was black in color and twisted one and one-half times from right to left on its pedicle. There was no communication with the liver except toward the common duct. Dr. Cramp presented the specimen removed, which bore no resemblance whatever to a gall bladder.

Removal of Tongue for Carcinoma.—Dr. CRAMP presented this patient. This man was admitted to the service of Dr. George Stewart at Bellevue Hospital on August 13, 1913. There was an ulcer on the left side of the tongue involving a small portion of the base of the tongue and having all the appearances clinically of an epithelioma. A section was sent to the pathologist, who pronounced it carcinoma. At the primary operation both lingual arteries were ligated and the tongue removed through the mouth. There was not a great deal of hemorrhage. The patient did not do well for a time after the operation because he could not swallow and his nutrition was thus interfered with. At a later operation several glands in the neck were removed, but according to the pathologist these were not involved in the malignant process. The first operation was performed on August 27, 1913, and up to the present time there were no evidences of recurrence.

Abscess of the Liver.—Dr. CRAMP presented this patient, who was admitted to Bellevue Hospital on October 23, 1913. He had been suffering from chills, chilly sensations, and pain all over the body, and had been ill for a week at the time of his admission to the hospital. He complained of pain in the right epigastric region, but no nausea, vomiting, or sweats. His temperature was 105° F. The local signs were not definite, though there was considerable resistance in the upper part of the abdomen. The leucocyte count was 23,000 and the polymorphonuclears 84 per cent. He was transferred to the surgical division and the following day the leucocyte count was 19,000 and polymorphonuclears 96 per cent. At operation a small protrusion was found at the right of the gall bladder containing pus. This was evacuated and found to contain staphylococcus aureus. The patient left the hospital on November 15, 1913, and had returned occasionally for observation, but up to the present time there had been no further trouble.

Hemorrhage from the Middle Meningeal Artery Due to Traumatism; Hemiplegia, Motor Aphasia; Osteoplastic Flap for Ligation of Vessel; Recovery.—Dr. M. S. KAKELS presented this patient. He stated that a violent injury to the skull sufficient to cause laceration of the intracranial vessels was generally followed by symptoms depending upon the situation and extent of the extravasation. In intracerebral injuries important centers might be involved and rapid death follow without giving the symptoms of compression. In extracerebral due to extravasation from the middle meningeal artery or its branches a peculiar and characteristic sequence of symptoms followed the traumatism to the cranium. These were (1) concussion, (2) a free conscious interval, (3) focal symptoms, and finally (4) symptoms indicative of general pressure, such as stupor, unconsciousness, slow pulse, rise in blood pressure and respiratory symptoms. The focal ymptoms were at first irritative and might progress to those of local paralysis of the same centers and if the clot was large enough to extend to the centers of the lower extremities, which were situated higher up on the hemisphere, hemiplegia might result. This, however, was extremely uncommon. The fact that the patient here presented had a lesion of this type, of which there were not many recorded, had prompted Dr. Kakels to report the case. This man, 45 years of age, was admitted to the Lebanon Hospital on October 11, 1914,

with the history of having been accidentally struck with a baseball while watching the game. After being struck he felt dizzy, but quickly recovered therefrom and walked to his home, where after an hour he became unconscious, and the whole right half of his body, including his face, was found completely paralyzed. When brought to the hospital there was a small hematoma over the left parietal region, but no depression could be felt. The right half of his face was smooth and lifeless. The left pupil was markedly dilated and did not react to light or accommodation. The right upper and lower extremities were paralyzed. The knee jerks, Babinski and ankle clonus were present on the right side. The left upper extremity was negative, while the left lower extremity exhibited knee jerks, but only slight ankle clonus. The patient was unconscious. Lumbar puncture revealed sanguinous cerebrospinal fluid under increased pressure. The pulse was slow and irregular, respiration was stertorous, and blood pressure 220 mm. The history and classical train of symptoms, namely, traumatism, concussion, free interval, and then compression, was typical of a rapid and large extradural hemorrhage, probably due to laceration of the middle meningeal artery or one of its branches. A horseshoe incision was made in the left temporal region. An osteoplastic flap was dislocated downward and an extensive clot, larger than the palm of the hand and over an inch in thickness, was found. The clot was so large and thick that when removed one could plainly see the depression in the region of the brain occupied by the hematoma. A fissure fracture of the temporal lobe was found close to the base of the skull. Active hemorrhage was coming from the middle meningeal trunk and from a small vessel on the dura. They were both ligated. The brain was seen to pulsate. There was no subdural hemorrhage over the exposed area, still there was some blood welling up from beneath, probably from laceration of some emissary vein. The brain was gently lifted and a considerable amount of clots were removed from the base of the skull. The space was gently packed with iodoform gauze to check the persistent oozing, the osteoplastic flap replaced and the scalp loosely sutured. The blood pressure had dropped during the operative procedure from 220 mm. to 110 mm. when the operation was completed. Forty-eight hours later, under narcosis, the old incision was laid open, the osteoplastic flap reflected and the packing carefully removed. There was no more oozing. A small rubber tissue drain was inserted through one of the trephine openings, which was removed on the seventh day when the wound was found perfectly healed. On coming out of his stupor the motor aphasia and hemiplegia were markedly in evidence. These manifestations gradually disappeared until at the end of two weeks they were hardly noticeable. The patient was then discharged fully recovered. The quick operative interference, about six hours after his injury, no doubt was the most important factor in his recovery. The speaker said that there were some conditions in which the exact place to open the skull baffled the operator. In such cases, as cited above, the making of a large osteoplastic flap with its center over the main trunk of the middle meningeal seemed quite advantageous and rational, as one thus obtained an excellent exposure of the main trunk and its branches. Beside, with such an opening one could lift the brain and thereby expose the middle fossa of the skull, giving a good view for basilar inspection and the removal of clots.

Operative Relief of Subacromial Bursitis with Calcareous Deposit.—Dr. Walter M. Brickner made this presentation.

Case I.—This patient was seen on July 24, 1913. He had been suffering from pain in the left shoulder for four months. Abduction was not possible and external rotation was limited. There was marked tenderness over the subcoracoid process. The *x*-ray showed a small shadow. In this case the bursa was aspirated.

Case II.—In this case there was no history of trauma, but the man was a builder and the probabilities were that he had sustained some slight injury. Abduction and rotation were impossible because of the pain. Operation gave prompt relief from the pain and abduction was helped, but it would take quite a while to restore the internal rotation. Before the operation the arm was absolutely useless because of the adhesions. This man's condition had been greatly improved by the operation.

Case III.—This patient was seen May 19, 1914. He was a paper hanger and gave a history of a dislocation four months previously. The pain was very severe, radiating up to the neck and down to the elbow. Internal and external rotation were limited and there was tenderness over the lesser tuberosity. He was operated on at Mount Sinai Hospital by the method described later. He had now been working for ten weeks; abduction was restored, and internal rotation restored for all practical purposes if not entirely so.

Case IV.—This patient was seen on October 4, 1914. He had sustained a fall, striking on the shoulder, but did not feel any ill effects until he raised the arm to strike when he had severe pain radiating to the forearm. Motion was most painful, internal rotation considerably limited, and there was atrophy of the deltoid and infraspinatus and supraspinatus muscles. The *x*-ray showed a calcareous deposit. The patient was operated upon on October 6th. The pain was relieved before the dressings were removed. He had not acquired normal motion as yet, but was using Indian clubs to restore internal and external rotation. This patient was not as bad as the other two had been and would probably make a complete recovery.

Case V.—This patient had sustained an injury, while lifting a hind quarter of beef and swinging it over his shoulder to a hook, five days before presenting himself. The pain in his shoulder was very severe, and there was practically complete scapulo-humeral fixation. The *x*-ray showed a deposit. He was much improved by treatment, but refused operation for the present. As long as the deposit remained he would continue to have pain.

Case VI.—This patient was a lady who presented herself in July last, suffering with intense pain in her shoulder. Abduction was *nil* and there was no rotation. The patient at first gave no history of trauma, but on further questioning admitted having hung to a car strap and while in this position slipping. When she got off the car she had severe pain in the shoulder. This had happened ten days previously. Three days after receiving the injury the pain became very severe. Both active and passive motion were very difficult. There was tenderness over the great tuberosity. The *x*-ray showed a typical deposit. She was operated upon and made an excellent recovery. She now had perfect motion with perhaps a little limitation of external rotation.

Prevalent Fallacies Concerning Subacromial Bursitis: Its Pathogenesis and Rational Operative Treatment.—Dr. Brickner presented this paper. He stated that all the articles on this subject presented misconceptions and gross fallacies. Among these fallacies was the idea that the thickened walls of the bursa cast the shadow on the *x*-ray plate; that the calcareous deposit was within the bursa; that the condition arose from a bacterium or a toxic product; that there was marked swelling over the tuberosity, and that excision of the bursa was a practical method of treatment. The writer had had nineteen cases with six operations and these had served to call attention to these fallacies. The thickened wall of the bursa cast no shadow, as was demonstrated by the fact that the bursa showed no shadow after the deposit was removed. Again, the calcareous deposit was not within the bursa but beneath it, on the supraspinatus tendon. In the fifth case reported the deposit was imbedded in the infraspinatus tendon near its tuberosity. In the sixth case it was around and in the supraspinatus tendon. It might be deposited in a tear in the tendon, but the tendon itself was not involved. This deposit resembled shad roe or yellow tartar, and, according to the analysis of S. Bookman, contained calcium oxylate, magnesium carbonate, blood fibrin, and serum albumin. These deposits had no sac or limiting membrane. The deposit might be semifluid. It had been stated that if the process was tuberculous the deposit was cheesy, but this was also an error. Again, these deposits were sometimes single and sometimes multiple and the fluid ones were larger than the shadow cast. The lime formation was not always slow, but might be apparently rapid, as in the one case in which it was observed four days after the accident. In all these cases operated on within a year and a half the calcareous deposit was in or on the tendon but not of it. The assumption of a bacterial or toxic origin had not been substantiated by any evidence. Traumatism between the acromion and the greater tuberosity was usually the cause of the injury, and it was furthermore frequently a mild injury, so light that the pain in the shoulder was not associated with it. It had occurred from falling on the outstretched arm or the deltoid. Many instances were not typical regarding the classical symptom of

tenderness over the acromion. The tenderness might be over the lesser tuberosity or interiorly. The diagnosis of these cases was not at all typical, and the *x*-ray was of the greatest importance in assisting in the differential diagnosis from brachial neuritis, arthritis, etc. In the acute cases with loss of function an open operation gave prompt relief; in less severe cases rest in bed, with the head of the bed elevated slightly and the hand tied to the head of the bed, so that the patient would very gradually slip down and the hand be gradually drawn upward, had been found very effective. Some had advised the excision of the entire bursa, but when one considered its size this was rather an extensive undertaking, and tuberculosis was the only indication for such a procedure. The writer said his method of operating was, with the patient on his back, to make an incision from the edge of the acromion directly down toward the elbow. The deltoid was split and, partly by blunt and partly by sharp dissection, the bursa was exposed and separated from the floor. If there were adhesions over the greater tuberosity they were divided with the scissors. The bursa was incised in the same line and if the calcareous deposit was found it was evacuated. Often there was a small tear in the tendon containing the deposit. If this was found to be the case it was washed out with salt solution. If the deposit was not found under the bursa the infraspinatus was opened and any deposit found there was removed. A very thin layer of vaseline was spread inside the bursa, which was helpful in preventing the formation of adhesions. The arm was put up in the abduction position in a light plaster cast at an angle of 120 degrees. This might be a little irksome to the patient, but was worth while. Dr. Brickner gave a lantern slide exhibit which showed the difference in the *x*-ray pictures between calcareous deposits and tuberculous and luetic processes.

Dr. Eli Moschcowitz showed lantern slides from three of the cases which Dr. Brickner had presented, and explained the findings. The central picture he said was first necrosis, then granulation tissue, and lastly calcification. The necrosis was easily explained by the small blood and lymph supply to the locality. Calcium formation occurred easily in dead or inert tissue. It was difficult to explain the calcareous deposit found in the one case a week after the injury. The calcium deposit might be due not only to the necrosed tissue, for which it had a predilection, but to defective metabolism. There were two conditions that might be compared with this, and these were gouty infiltration and myositis ossificans. In bone formation there was a preliminary calcification and it was probable that they should some days find bone in these deposits.

Dr. Reginald H. Sayre said he wished to emphasize the necessity of taking the *x*-ray photographs with the arm everted. He showed two *x*-ray pictures taken of the same arm within a few moments of each other; the one showed the calcium deposits and in the other there were apparently no such masses.

Dr. R. H. M. Dawbarn said that in connection with the diagnosis of tuberculous disease one author stated that when the *x*-ray photograph was poor and the edges of the bone looked woolly it was pretty definite evidence of tuberculosis.

Dr. George D. Stewart made preliminary report on a case in which he had recently operated, removing 181 calcareous bodies from the bursæ of the shoulder joint. As the patient was still in the hospital the full report would be presented later.

Dr. R. H. M. Dawbarn said he had never seen anything like the case just reported, but he had seen an analogous condition of the knee joint, although the masses were not so smooth and regular as these which Dr. Stewart had just shown.

Dr. William H. Stewart said he wished to emphasize the importance of taking radiographs of the patient in more than one position; they should be taken with the joint, at rest, in the abduction position, and the position of internal rotation, and then if calcareous deposits were present they would be seen. He expressed surprise that Dr. Brickner had said what he did of a calcareous deposit having taken place in four days; this scarcely seemed possible, and he regretted that an *x*-ray had not been taken before the injury occurred.

Dr. Edwin Beer observed that Jellinghaus had shown that calcium was deposited along the suture line of a wound in five or six days. As to Dr. Brickner's indications for removal of the bursa, he would like to add sarcoma.

Dr. A. J. Brown said that it appeared a little difficult to understand that a tissue could pass through the stages of necrosis, repair by granulation, and subsequent calcification, as described by Dr. Moschcowitz, and the entire process be completed in four days. Four years ago a series of cases was reported by Dr. Haenisch of Hamburg, in which the findings, both radiographically and operatively coincided with those of Dr. Brickner. Several cases cured by non-operative means presented no pain, though the calcareous mass shown by *x*-ray was still present. This led him to radiograph both shoulders in acute cases and in two he found the shadow of a calcareous mass present in both shoulders, which would make it appear that the prominent symptom, pain, is due rather to the grafting of an acute process on a chronic one than to the presence of a calcareous mass *per se*.

Dr. A. Ernest Gallant asked Dr. Brickner why he kept the shoulder immobile for ten days. Would not function be restored much earlier if massage and passive motion were begun earlier? He also asked whether Dr. Brickner used the abduction position in these cases.

Dr. Brickner said that Dr. Sayre's point was well taken; the *x*-ray pictures should certainly be taken in different positions. With reference to the case in which the deposit was noticed after four days, he had been careful not to say that it had occurred within the four days, but that it was found at that time. He would like to ask if anyone had seen a case with such a deposit in which the patient had no symptoms referable to the shoulder. Slight causes were apt to result in the crushing of the tendon between the two bones, and, as had been pointed out, the region was prone to such deposits. In reference to Dr. Gallant's question as to whether he used abduction position in treating these cases, he had replied in the affirmative in his paper.

A New Operation for Stricture of the Rectum or Sigmoid.—Dr. Joseph Wiener presented this communication. After reviewing the varieties of stricture, he stated that, with the exception of the neoplastic and congenital, they might all be included under the general term inflammatory. He then reviewed the seven methods of treatment hitherto employed for the treatment of strictures of the rectum and pointed out their disadvantages. None of them seemed to him the ideal procedure in the following case. This patient came under Dr. Wiener's care in Dr. Lilienthal's service at Mount Sinai Hospital. He was sixty-three years of age and had complained of gradually increasing asthma for the past twelve years. He had had a reducible hernia for fourteen years and had been operated on five years previously for vesical calculi. Four months before admission he had resorted to a hot enema for constipation and produced a severe burn. A few weeks later he noticed small frequent bowel movements, which soon became painful. They were no doubt the result of the formation of the inflammatory stricture. A proctitis developed. The man's general condition was not good. He had extensive emphysema, chronic bronchitis, an enlarged heart with systolic murmur at the apex, marked arterio-sclerosis, and was somewhat cyanotic and dyspneic. On recital examination, five inches from the anus a hard circular infiltration was felt, which would not admit the tip of the index finger. The tip of the smallest bougie could not be passed through it. All rectal manipulation was very painful. The stricture was too high up to make linear incisions, any attempt at dilation would probably have resulted in perforation of the rectum and an external proctotomy with resection of the coccyx would have been far too serious an operation for this debilitated man. They finally decided to open the abdomen and to be guided in their operative procedure by the pathological condition present. The abdomen was opened by a left rectus incision. A Wales bougie was inserted by an assistant and found to be obstructed about five inches from the anus. At the site of the stricture a white scar about one inch wide was seen, completely encircling the bowel. The assistant was instructed to make considerable upward pressure on the bougie, which the writer made to engage in the stricture by manipulation from the inside of the abdomen. This was at first not successful, but it occurred to Dr. Wiener that by forcing the bowel downward towards the anus from within the abdomen, he might overcome the stricture. After a few minutes manipulation he felt the stricture begin to dilate and soon felt the tip of the bougie in the bowel above the stricture. Larger bougies were then successively passed, the bowel being milked over them as with the first, until the largest Wale bougie lay in the rectum above the stricture, where it was

allowed to remain and the abdomen was closed. Eighteen hours after the operation the bougie was removed on account of pain. Convalescence was uninterrupted. The man was requested to return every few weeks to have bougies passed, but this he neglected to do; nevertheless the largest Wale bougie could be passed without difficulty four months after the operation. This operation was applicable to all strictures more than three or four inches from the anus. Its advantages were: (1) ease and certainty, the work being done under the guidance of the eye; (2) absence of shock; (3) rapid recovery; (4) little or no danger of perforating the rectum.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEW YORK STATE BOARD OF MEDICAL EXAMINERS.

May, 1914.

(*Continued from page* 42.)

CHEMISTRY.

Answer a total of 10 of the questions on this paper but no more.

Candidates must answer each of the first six questions.

1. Give an example of each of the following: normal salt, acid salt, basic salt, double salt.
2. Give the formula, the physical properties and the chemical properties of nitric acid.
3. In what various forms does carbon occur?
4. Give the chemical distinction between hard water and soft water.
5. Give the occurrence in nature, properties, compounds and uses of sodium.
6. Describe the preparation of diastase. What is its action on starch?
7. What are the properties of glycogen and where is it found?
8. Define (*a*) pasteurization, (*b*) modified milk.
9. Describe the urinometer.
10. Define (*a*) mixture, (*b*) compound, (*c*) atomic weight, (*d*) base, (*e*) salt.
11. Write the symbol of each of twenty elements and the formula of each of ten compounds, giving the name in each case.
12. Give in detail a method of estimating the amount of sugar in urine.

HYGIENE AND SANITATION.

Answer a total of 10 of the questions on this paper but no more.

Candidates must answer each of the first six questions.

1. What is an antiseptic? Give two examples.
2. What are the important objects of the registration of vital statistics?
3. What means may be taken to prevent the spread of tuberculosis?
4. What are the principles of a proper system of ventilation?
5. What infectious diseases may be communicated by drinking water?
6. To what diseases does the habitual use of alcohol cause a predisposition? What effect has the use of alcohol on longevity?
7. Describe in detail the septic tank method of purification of sewage.
8. What are the objections to hot air furnaces and how may these objections be overcome?
9. How is the spreading of infectious diseases among school children guarded against?
10. In what occupations is lead poisoning liable to occur?
11. What are the arguments in favor of public baths in large cities?
12. What have been the benefits to mankind of vaccination in preventing smallpox?

SURGERY.

Answer a total of 10 of the questions on this paper but no more.

Candidates must answer each of the first six questions.

1. Describe a dislocation of the hip and give directions for its reduction.
2. What special precautions should be taken in the case of burns about joints to prevent contractions?
3. Give the surgical treatment of incipient tuberculosis of the knee joint.
4. Give the symptoms of deep stitch abscess following laparotomy.
5. Give the symptoms of duodenal ulcer. What is its most frequent location?
6. Give the symptoms of fracture-dislocation of the second lumbar vertebra.
7. Describe a method of skin-grafting for extensive denudation (omit details of aseptic technique).
8. Describe the steps of an operation for indirect inguinal hernia (omit details of aseptic technique).
9. Describe three methods of opening the abdomen to remove the vermiform appendix (omit details of aseptic technique).
10. Give directions for the measurement of both femurs for discovering shortening by fracture or by disease.
11. Describe ectropion and an operation for its relief.
12. Name the important sequelæ of purulent otitis media.

ANSWERS.

CHEMISTRY.

1. A *normal salt*, Na_3PO_4; an *acid salt*, Na_2HPO_4; a *basic salt*, PbOHNO$_3$; a *double salt*, $Mg.NH_4.PO_4$.

2. NITRIC ACID. *Formula*, HNO_3. *Physical properties:* A colorless liquid which boils at 186° F. and solidifies at 40° F.; it gives off white fumes in damp air, and has a strong acid taste and reaction. *Chemical properties:* a strong oxidizing agent; is decomposed on exposure to heat, light, or air; with most of the metals it forms nitrates; it oxidizes and destroys most organic substances.

3. *Carbon occurs:* (1) as diamond; (2) as graphite; (3) as charcoal.

4. *Hard water* contains excess of calcareous salts; *soft water* does not. If the hardness is due to a bicarbonate, it is said to be *temporary;* if to a *sulphate*, it is called *permanently hard.*

5. *Sodium* occurs chiefly as the chloride; also as carbonate, sulphate, nitrate, and in borax. *Properties:* A soft, silver-white, waxy metal; it tarnishes readily on exposure to air; it burns with a yellow flame, and is a strong reducing agent; at the ordinary temperature it decomposes water, with evolution of hydrogen. *Compounds:* oxide, dioxide, hydroxide, chloride, bromide, iodide, nitrate, sulphite, two sulphates, thiosulphate, three phosphates, tetraborate, chlorate, manganate, permanganate, acetate, two carbonates. *Uses:* It is used as a reducing agent; also in the manufacture of sodium dioxide and of cyanides.

6. *Diastase* is produced during the germination of grain. Pancreatic diastase may be extracted from the pancreas by salicylated water or glycerol. It converts starches into sugar.

7. *Glycogen* is found in the liver, placenta, leucocytes, cartilage, muscle, pus cells, and some embryonic tissues. Glycogen is a white powder, amorphous, odorless, and tasteless; soluble in water; insoluble in alcohol or ether; its solutions are dextrogyrous.

8. *Pasteurizing* milk consists in heating it to a temperature of 167° F. for a period of twenty minutes.

Modified milk is cow's milk that is any way changed so as to make the proportion of the ingredients more closely resemble what is found in mother's milk.

9. The *urinometer* is a hydrometer used for the purpose of obtaining the specific gravity of the urine. It consists of a hollow glass vessel weighted at the body and furnished at the top with a long graduated stem, and is so adjusted that the instrument floats at the required level. A cylinder to hold the urine (in which the hydrometer is floated) is also required. The temperature of the urine should be 15.5° C.

10. A *mixture* is the product obtained by uniting into a more or less homogeneous whole two or more substances, whether elements or compounds.

A *compound* is a substance made up of two or more elements, chemically united, in definite proportions.

Atomic weight is the weight of an atom of an element as compared with the weight of an atom of hydrogen.

A *base* is a ternary compound capable of entering into double decomposition with an acid to produce a salt and water.

A *salt* is a substance formed by the substitution of an electropositive element or radical for part or all of the replaceable hydrogen of an acid.

11. Hydrogen, H; oxygen, O; nitrogen, N; carbon, C; silver, Ag; chlorine, Cl; potassium, K; sodium, Na; sulphur, S; bromine, Br; iodine, I; phosphorus, P; arsenic, As; antimony, Sb; gold, Au; iron, Fe; manganese, Mn; lead, Pb; mercury, Hg; tin, Sn.

H_2O, hydrogen monoxide; H_2O_2, hydrogen dioxide; H_2SO_4, sulphuric acid; $KHSO_4$, monopotassic sulphate; K_2SO_4, dipotassic sulphate; HNO_3, nitric acid; H_3PO_4, phosphoric acid; NaCl, sodium chloride; $CHCl_3$, chloroform; $(C_2H_5)_2O$, ether.

12. *To estimate the amount of sugar in urine:* The specific gravity of the urine (at 77° F.) is taken; some yeast is then added, and the mixture is kept at 77° F. till fermentation is complete; the specific gravity is again taken, and it will be found lower than before. Each degree of diminution in the specific gravity denotes 0.22 gram of sugar in 100 c.c. of urine.

HYGIENE AND SANITATION.

1. *Antiseptics* are agents which prevent the growth and activity of microorganisms; *examples:* bichloride of mercury (in weak solution) and salicylic acid.

2. *The important objects of the registration of vital statistics* are: To point out where and to what extent disease and death are on the increase; to suggest suitable sanitary measures; to furnish a basis for the study of many social problems; to furnish the necessary data for life insurance.

3. "The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation for the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) The enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals. The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk."—(Parkes' *Practical Hygiene.*)

Further, the patient should be duly impressed with the communicability of his disease; he should be particularly warned about the disposal of sputum, the use of handkerchiefs, etc.; he should cover his face when sneezing or coughing; kissing should be prohibited. Rooms should be well ventilated and frequently cleansed. Clothes and bedclothes should be boiled or disinfected before being sent to the laundry.

4. *Principles of ventilation:* (1) There must be a constant stream of pure air admitted into the room. (2) The inlets and outlets should be placed as far apart as possible, so as to allow of proper diffusion throughout the room. If possible they should be placed on opposite sides of the room with natural ventilation, but on the same side with artificial ventilation. (3) The inlets for cold air must discharge some five or six feet above the level of the floor, and the outlets for vitiated air must be near the ceiling. (4) The admission of warm air can be permitted near the floor. (5) The incoming air should be itself pure and of sufficient quantity. (6) The inlets for each person in the room must equal in total area 24 square inches, and the outlets should contain the same area. (7) The incoming air must not produce a draught. (8) The ventilation of a large room is always easier than that of a small one. (9) A large room will not compensate after the first hour for a proper system of ventilation. (10) If proper inlets and outlets are constructed, all other means for the admission of air should be closed. (11) The windows of all unoccupied rooms should be opened wide so that they may be flushed with a stream of pure air.—(From Evans' *Student's Hygiene.*)

5. *Infectious diseases which may be communicated by drinking water:* cholera, typhoid, dysentery, paratyphoid.

6. *The habitual use of alcohol predisposes to:* Arteriosclerosis, chronic nephritis, cirrhosis of liver and kidneys; it lowers the resisting power against bacterial invasion, hence pneumonia, tuberculosis, etc., may be included in this list. The excessive use of alcohol shortens life; the moderate use probably has no effect on longevity, but much depends on the constitution and habits of the individual.

7. *A septic tank* is a specially constructed tank for the treatment of sewage; in it the sewage as such is destroyed, and new substances are built up in its place. In *Cameron's septic tank* system "the sewage is first led into a tank from which air and light are excluded. Digestive changes take place in the sewage within this tank as the result of anaerobic bacterial action, which is favored by the darkness, the absence of air, and the perfect stillness at which the sewage is maintained. Under these circumstances much of the solid matter is rendered soluble and dissolved."—(Notter and Firth.)

8. *Objections to hot air furnaces:* The objection to cast-iron furnaces and stoves is that carbon monoxide is believed to escape through invisible fissures in the plates and joints, while the heaters are red hot; hence they should be lined with fire clay; this precaution may not be necessary for the escape of CO, but it will improve at least the quality of the heat. Since all heaters are liable to render the air too hot and dry, they should be provided with evaporating pans, or, what is even preferable, a larger heater should be chosen which will not have to be raised to red heat and at the same time furnishes a larger volume of warmed air. If the air is superheated it acquires a peculiar odor, probably due to charring of organic dust; it also becomes very dry and irritating owing to the rapid evaporation of moisture from the skin and mucous surfaces of the inmates and in consequence is apt to produce catarrhal affections, conditions which do not prevail when the temperature of the air delivered does not exceed 90°. Dampers in the smoke flues of heaters are always objectionable; the joints of the draft doors should be so good that opening and closing of the lower door or slides is sufficient, but as long as these joints are imperfect dampers are a necessary evil.—(From *Reference Handbook.*)

9. *The principal means of preventing the spread of infectious diseases in schools* are: Regular and efficient inspection by physicians; prompt exclusion and isolation of anyone suffering from an infectious disease, or coming from a house where such disease is; compulsory vaccination; compulsory notification of all infectious and contagious diseases; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease, or who have come from a house where such disease prevailed, should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

10. *Lead poisoning is liable to occur in the following occupations:* Lead smelting, making and handling lead carbonate, making electric accumulators, special printing and electrotyping processes, removing dry paint by sandpapering or chiseling, and painting in general; lead mining and refining, plumbing, and soldering, paint manufacture, shot making, polishing cannon balls and shot, making lead coffins.—(From Thompson's *Occupational Diseases.*)

11. Public baths are necessary when private baths do not exist or are not available. It is better to take a public bath than not to bathe at all.

12. "The beneficent results of the introduction of vaccination into this country are well shown by a comparison of the conditions obtaining in the early part of the eighteenth century and in the corresponding period of the nineteenth in Boston. In 1721, Boston, with a population of about 11,000, had 5,989 cases of smallpox with 850 deaths. In 1730, in a population of about 15,000, there were about 4,000 cases with 509 deaths; but between 1811 and 1830, in a very much larger population, there were but 14 cases of the disease. In London, during the third quarter of the seventeenth century, the average annual mortality from smallpox per million was 4,000. A hundred years later, between 1,770 and 1,780, it was more than 5,000; in the first years of vaccination, it was more than 2,000; by the middle of the nineteenth century it fell to about 500, and in the last decade of the century to less than 75. In the whole of England, during the period of optional vaccination, the mortality rate fell from about 2,000 to 417, and after the practice was made compulsory in 1850 it fell to 53."—(Harrington's *Hygiene.*)

SURGERY.

1. *Dislocation of the hip on to the dorsum ilii:* "The head of the bone may be felt on the dorsum ilii, unless the patient is very fat or very muscular. The leg is in a position of flexion, adduction, and inversion, and the ball of the toe rests on the other instep. The great trochanter lies above Nélaton's line, and is nearer to the anterior superior spine than that of the sound side. The limb is shortened two or three inches, and there is a marked hollow over the front of the joint. *Treatment.*—The patient is placed on a mattress on the floor and anesthetized. The leg and thigh are flexed in the position of adduction. This rolls the head down to the lower part of the acetabulum. The leg is then circumducted outward and brought down straight; this carries the head through the rent into the acetabulum. Failing success by this method, the body must be fixed and direct upward traction must be exercised upon the flexed thigh. As a rule these maneuvres are successful; if not, extension by pulleys must be made use of." —(*Aids to Surgery.*)

2. In case of *burns about joints* special care must be taken to prevent subsequent contractions which may interfere with the movements of the joint. This is accomplished by Thiersch's method of skin grafting.

3. *Incipient tuberculosis of the knee joint* requires rest, with application of splints, extension, and the application of a plaster of Paris bandage. Bier's method of hyperemia may be tried, and tuberculin (after the opsonic index has proved suitable) has been recommended.

4. *Symptoms of deep stitch abscess:* At first there is a slight but persistent rise of temperature accompanied by an increased pulse rate; later on, the presence of pus may give rise to the symptoms of septicemia or peritonitis with collapse.

5. *Symptoms of duodenal ulcer:* Pain of a dull aching character, felt to the right of the midline, and coming on about three or four hours after meals; vomiting; blood may be passed with the feces, or hematemesis may occur. It is most frequently located in the first part of the duodenum, being that part which is acted on by the acid chyme from the stomach.

6. *Fracture-dislocation of the second lumbar vertebra:* There will be motor paralysis of both lower extremities; anesthesia of both lower extremities, and gluteal, and perineal regions; incontinence or dribbling of urine; incontinence of feces.

7. The *Ollier-Thiersch method of skin grafting* is performed as follows: "Thoroughly asepticize the ulcer, the surrounding skin, and the site from which the graft is to come (the inner side of the arm or the thigh), and wash away the mercurial preparation with normal salt solution. Apply dressings wet with salt solution. On bringing the patient into the operating room remove the dressings from the ulcer, scrape the ulcer and its edges, irrigate with salt solution, and compress to arrest hemorrhage. Grafts are then obtained by putting the prepared skin upon the stretch and cutting strips with a razor. While the razor is being used the part is constantly irrigated with salt solution. Mixter's apparatus enables one to perform this operation with great neatness and speed. This apparatus consists of a knife and an open square with sharp points on the under surface. The square is forced down upon the front of the thigh, the epidermis mounts up in the opening to above the level of the metal sides and the grafts may be cut with ease. The graft contains the epidermis, the rete, and part of the true skin. In Halsted's clinic the skin of the thigh is made tense by pressing upon it with a piece of ascepticized wood, the wood is drawn slowly along, and is followed closely by the sharp catlin, with which the surgeon cuts long grafts. The grafts are pressed into place upon the raw surface, and each graft overlaps a little the edges of the wound and the adjacent grafts. The skin wound is dressed antiseptically. Recently it has been suggested that a ring of aseptic gauze be made to encircle the limb below the grafted area, and another ring above the grafted area; on these pads little strips of wood wrapped in aseptic gauze are so laid as to make a cage, and around this cage the dressings are applied (moist chamber plan)."—(Da Costa's *Modern Surgery.*)

8. *Bassini's operation for the radical cure of oblique inguinal hernia:* "The incision begins at a point to the inner side of the anterior superior iliac spine, and about one-half inch above Poupart's ligament, passes obliquely downward parallel with and about one-half inch above Poupart's ligament, and ends over the middle of the external abdominal ring, being about three to three and one half inches long. Divide skin and superficial fascia, clamping bleeding vessels, and retract edges of wound, exposing aponeurosis of external oblique. Demonstrate the external abdominal ring and pass a grooved director through its opening and carry it obliquely upward in the line of the fibers of the external oblique aponeurosis, and immediately beneath its surface, for a distance of about two and one-half inches, the instrument showing through its thin texture. Slit up the fibers of the aponeurosis of the external oblique upon the grooved director with a scalpel, traveling in the cleavage line of the fibers. Dissect, by blunt separation, the upper edge of the cut aponeurosis inward and upward nearly to the outer edge of the rectus sheath. Similarly dissect, by blunt separation, the lower edge of the cut aponeurosis of the external oblique downward and outward to the shelving portion of Poupart's ligament. The inguinal canal, except that part covered by the internal oblique, is thus exposed. Grasp, with forceps, aided by the fingers, the mass of soft tissues just within, or emerging from the external abdominal ring, composed of cord and hernial sac, and, pushing aside the muscle-fibers with a blunt dissector or closed ends of blunt, curved scissors, lift upward and outward the hernial sac and cord, drawing them partly from the direction of the inguinal canal, and partly from the direction of the scrotum, the hernia lying anteriorly, surrounded by the infundibuliform fascia, and the cord posteriorly, the sac and cord being more or less intimately adherent. Isolate the sac from the cord by blunt dissection and carry on the freeing of the sac upward, retracting the internal oblique muscle outward to expose the outer aspect of the inguinal canal, until the sac begins to open out into the general peritoneum. If it be certain that the sac contains no adherent intestines or omentum, it need not be opened. If there be any question, and it is probably better in all cases to do so, whether question or not, the sac should be opened at some distance below the point of intended closure and examined. The contents of the sac, if any, are returned to the abdominal cavity. The sac is then to be treated in one of two ways: If it be small, a double chromic gut ligature is carried through the center of that portion which is to form the line of occlusion; these two ligatures are crossed and are firmly tied on each side, and the sac cut off a safe distance from the ligatures. If the sac be large (so that ligating would cause too much puckering and probably slip off), its surfaces are to be sutured with chromic gut on a level with the site of division, and then cut off with scissors at a safe distance distal to the suture line. The sac is thus disposed of and returned to the abdominal cavity. The cord is now taken up in the left thumb and index and isolated from external to internal ring, *en masse*, without disturbing its component structures, and a strip of gauze is passed beneath it—whereby it is held up by an assistant well out of the way, until its new bed is made for it. The lower borders of the internal oblique and transversalis muscles are now sutured to the shelving portion, or border of Poupart's ligament, with interrupted sutures of kangaroo tendon or chromic gut, taking a good hold of both structures, using a curved needle, preferably of the Hagedorn type. Prior to the insertion of the sutures uniting internal oblique and transversalis above to Poupart's ligament below, the lower borders of the internal oblique and transversalis should be isolated by the surgeon's fingers from the transversalis fascia, beginning at the conjoint tendon and extending outward to the internal abdominal ring. While passing the sutures, the surgeon's left index finger should be carried behind the conjoint tendon and also behind the lower borders of the internal oblique and transversalis muscles, so as to guide the needle-point. The first suture, near the upper end of the wound, pierces the internal oblique almost as far outward as the external border of the rectus muscle. It should just come in contact with the inner aspect of the cord when the latter is held at a right angle to the plane of the internal oblique muscle as it emerges from opposite the internal ring. A second suture is placed just above the cord, to strengthen the internal ring, the cord thus emerging between two sutures. As many similar sutures as are indicated (generally six or seven altogether) are thus placed. The last, lowest, suture passes through the conjoint tendon of the internal oblique and transversalis above, and the shelving portion of Poupart's ligament below. The cord is now dropped down upon its new bed made by suturing the conjoint tendon and the internal oblique and transversalis muscle to

the shelving border of Poupart's ligament. The separated edges of the aponeurosis of the external oblique are now sutured directly over the cord with continuous kangaroo or chromic gut sutures, carefully avoiding too tightly suturing the edges over the cord at the lower end, the new external ring, where the cord escapes into the scrotum. The skin is closed throughout with interrupted sutures of fine catgut. No drainage is used. The first dressing usually comes off at the end of a week."—(Bickham's *Operative Surgery.*)

9. *Three methods of opening the abdomen to remove the vermiform appendix:* (1) *McBurney's intramuscular ("gridiron") incision.* Having divided skin and fascia, the various musculoaponeurotic planes of the abdominal wall are divided in the order encountered and in a line with the muscular and tendinous fibers composing those planes, thus avoiding the division of any important nerves, the transverse division of any of the component muscular fibers, the retraction of transversely cut muscular and tendinous fibers, and,therefore, avoiding the consequent paralysis of parts supplied by several nerves, and weakening of cut muscles. (2) *The Battle-Jalaguier-Kammerer method* consists, after a vertical incision of skin and fascia, in the vertical division of the anterior layer of the sheath of the rectus, with the retraction of the entire rectus inward, followed by the vertical division of the posterior layer of the rectal sheath, somewhat nearer the median line, together with the subserous areolar tissue and peritoneum. At the end of the operation the rectus is allowed to resume its normal position, and the divided rectal sheath is repaired. (3) *Meyer's "Hockey-stiek" incision.* A method of entering the lower anterolateral abdominal cavity, partly by intramuscular separation, partly by transverse division of muscle, by means of an incision shaped somewhat like a "hockey-stick." Resorted to for the purpose of gaining a greater degree of exposure of the abdominopelvic cavity than afforded by the simple McBurney incision.—(Bickham's *Operative Surgery.*)

10. "The degree of shortening can be determined by measurement of the limbs from the anterior superior spine of the ilium to the lower border of the inner malleolus, and comparison with that of the opposite limb. Both limbs should form the same angle with the pelvis when the measurements are made and should be brought as close to the median line of the body as possible."—(Eisendrath's *Surgical Diagnosis.*)

11. "*Ectropion* is an eversion of the lid with exposure of more or less conjunctival surface. It may affect the upper or the lower lid, or both. *Symptoms.*—Epiphora (from eversion of punctum) causing excoriations and eczema of the lower lid, which, in turn, through contraction, increase the deformity. The exposed conjunctiva becomes reddened and hypertrophied. In marked cases the cornea may suffer, as a result of imperfect closure of the lids. *The V-Y operation (Wharton Jones).*—A V-shaped incision is made with the apex directed away from the palpebral margin, the incision including the cicatrix. The skin is freed from underlying parts, not only in the V-shaped area, but also to either side. The V-shaped area is slid upward until slight inversion of the lid margin is produced. The margins of the incisions are then brought together by sutures in such a manner that the figure Y results."—(May's *Diseases of the Eye.*)

12. *Important sequelæ of purulent otitis media:* Meningitis, subcranial abscess, thrombosis of lateral sinus, abscess of cerebrum or cerebellum.

(*To be continued.*)

Frontal Sinusitis in a Girl Aged Seven.—D. McKenzie reports this case. About three months before the child was brought to the hospital she was overturned by a bicycle and thrown on her face. A fortnight later pain and swelling in the left supraorbital region and around the left eye set in, together with headache and pyrexia. After about ten days of fever and headache, the patient being confined to bed, a sudden gush of pus from the left nostril took place. Thereupon the pain ceased, the fever left her, and the child was able to be up and about, but the discharge from the nose continued. When she came to the hospital pus was seen to be oozing freely from under the left middle turbinal. A skiagram showed well marked frontal sinuses on both sides, and the left frontal sinus, together with the left antrum, threw shadows. Treatment was confined to nasal drainage; the left middle turbinal was removed and nasal antrostomy performed, and the discharge gradually ceased.—*Proceedings of the Royal Society of Medicine.*

THE SYMPATHETIC NERVOUS SYSTEM AND THE GASTROENTERIC FUNCTIONS

BY CHARLES SUMNER FISCHER, PH.D., M.D.,

NEW YORK.

THE influence of the vegetative nervous system upon all organic functions has received such impetus from the investigations of the last decade that its importance as an etiological factor in the production of disturbed alimentary functions should command greater attention than at present exhibited. The tendency of gastrological effort during recent years to devote itself almost exclusively to the determination of the anatomical aspects of the subject has resulted in a neglect of interest in the functions as such. Whereas the vagaries of the latter have oftentimes been exploited *ad absurdum*, their finer discrepancies unduly emphasized as clinical entities, very little attempt has been made to attack these discrepancies in the light of etiological relationship. The fundamental principles here involved have seemed sufficiently explained provided the distinction was made between the organic and the functional aspects of a given case, generally with a slight stigma attached to the latter. The preference given to either of these aspects was oftentimes not determined by the facts, but rather by the psychological setting of the investigator. If he were a practical individual the theoretical necessities of purely functional disturbance could not satisfy his scientific craving for truth. In short, all truth could only appeal to him in a structural or tangible form. On the other hand, he, whose interest stimulated him to seek for causes beyond the concrete local evidence, was forced to admit that he was handicapped by lack of proof of contentions for whose justification he could offer only certain vague conceptions of nervous control.

Nevertheless, it must have been evident to all those whose interest in the subject of gastroenterology is not exclusively and immediately practical, that certain influences exist, certain constitutional trends, out and beyond definite physical and chemical forces, which have a direct bearing upon the production of organic disease. The great mass of chronic digestive disturbances exhibit fairly well defined tendencies of functional activity, certain fairly constant organic changes, possible of classification, which must receive their impetus from common influences conditioned by daily habit and environment. Furthermore, it is well established that identical assaults upon the alimentary health of different individuals will oftentimes result in opposite types of secretory and motor disturbances. It is also possible to assume that the great majority of the ordinary digestive diseases start as functional defects, either diminished or exaggerated, and reach to the dignity of organic change only as the result of the protracted existence of these. Hence it is, that the pertinent need in gastroenterology, for the time being at least, is a return to a more thorough consideration of the functions, not in the sense of finer subdivision of manifest activity, but with a view to a more intimate knowledge of the relation existing between functional change and the etiological factors bearing upon this. Of paramount importance in this connection have always been those operating through the nervous system.

The connection of the latter with the functional defects observed in the various local conditions has always been tacitly admitted, being forced upon us by Pavlov's work, but the practical spirit of the times has rendered the subject somewhat taboo. Too assiduous appeal to this phase of the work has undeservedly created the suspicion of personal ignorance or of evasion, with the result, that many have been afraid to grant it anything but scant courtesy. Notwithstanding that fifty per cent. of the acid gastric secretion is psychic, at least dependent upon hedonistic approach, the tendency has been to neglect this factor as an influence worthy of consideration. The literature upon this subject is comparatively sparse, and that which has appeared from time to time has come from sources non-gastrological. The appeal has generally fallen upon deaf ears, not because an adequate basis for the same has not been admitted, but because the insistent demand for a material and tangible causation of all digestive diseases has obscured a proper and comprehensive perspective of the whole field. The philosophical tendency of the times is one of pragmatism and mechanical construction and gastroenterology has responded very generously to this conception.

The intimate relationship between man's emotional state and the operation of his primitive instincts is axiomatic. In the domain of sex this has been overdetermined in recent years. In the field of self-preservation, that is, nutrition, it has been neglected, this notwithstanding certain very good evidence that the proper selection of nutritional elements is a matter of inherent protoplasmic activity of the original cell. However this may be, it is evident that psychic and nervous influences are oftentimes the controlling factors in the determination not only of the character but of the organic development of digestive diseases. Should anyone doubt this, let him subject the average run of cases in our gastric clinics, without selection as to physical examination or chemical analysis, to a vigorous course of treatment directed solely to the nervous system. The percentage of improvement will be surprising; or, given an average case of chronic dyspepsia, why does it improve under the treatment of one and not of the other? The physical and

chemical facts are plain. It does not require extraordinary skill to elicit these. The methods for doing this are monotonously exploited in every textbook and are common property. Treatment, medical, dietetic, physical, does not admit of much choice. It is determined by the facts in the case. Hence, the difference in the results obtained must be due to other factors. In truth, success will attend those efforts which go beyond the ordinary methods of procedure, and accrue to him whose conception is broad enough to comprehend the case in its broadest non-gastrological aspects. This is a personal matter, both for the investigator and the investigated. Generalization is impossible for it comprises an analysis of the individual's life, his habits, both of body and mind, the unavoidable insults of daily life calculated to influence his affectivity, the reactional trend of his nervous system, its inherent weakness and defects, and, having determined all these facts, to reveal the particular incidents of daily life and enforced environment which have a direct bearing upon the production of these conditions and defects. Most people are subjected to the same insults. Why does this particular individual succumb? Success will come to him who possesses the patience, interest, and ability to ferret out the secret and whose personality is such that he can control the situation.

Much of the lack of confidence and interest in the various phenomena associated with nervous influences in connection with digestive disturbances has been due in large measure to want of knowledge of the channels through which these influences operate. There has been no means by which the chasm between the insult and the effect could be bridged. The connection has been keenly noted and described by such writers as Rosenbach, Dubois, Dejerine, Gauckler, and Zbinden, but was of such hypothetical nature as to beg for confidence. It remained for later anatomists and physiologists to produce the actual physical basis for acceptation and confirmation of these observations. The anatomical and physiological investigations of the sympathetic nervous system by Langley and his coworkers, its pharmacological and clinical aspects, as developed by Eppinger and Hess, are matters of such far reaching importance for gastroenterologists in general that any neglect, misconception, or aloofness pertaining to this phase of the subject can only be condemned. The time for a vague diagnosis of neurasthenical or hysterical functional disturbances of the alimentary processes is past. By the now possible determination of the reactional trend of the sympathetic nervous system in each individual case, the intelligent gastrologist is in position to harmonize the eccentricities of function with the heretofore illusory influences bearing upon function. Nor does this apply to functional conditions alone,—it applies very acutely oftentimes to well-defined organic conditions, those demanding surgical interference. Many of these have started as simple functional defects. Given certain of such functional defects, knowing the reactional trend of the nervous mechanism controlling the functions, and fully cognizant of the daily avoidable or unavoidable insults of the individual's life and environment, renders it possible not only to trace the development of a lesion to its origin, but more important still, to be able to predict with a certain degree of assurance to what limits such functional defects will go, provided their tendency is not controlled. It is in the latter field that the most hopeful work lies, in the adjustment of the daily life of the individual to the inherent defects and weaknesses of the mechanism controlling the functions. In this regard, to determine assiduously the degree of functional change is unimportant. The hyperchlorhydria of one individual may be the normal acidity of another. Far more important is it to determine why a certain quantity of acid constitutes a hyperchlorhydria for one individual and not for another. This is the real problem and it is in the possibility of its solution that the real value of the most recent advancement of our knowledge lies.

In the present article the writer simply attempts to focus attention upon this phase of gastroenterology, to beat, as it were, a shapeless mass of literature into some sort of utilizable form, to reduce, if possible, the already known and given facts to a practical working basis. To be of any service these facts should be as accessible to and as ingrained in the mind as, for instance, the much exploited size, shape, position, and acidity of the stomach. It should be possible for every examiner in the course of the routine investigation of a given case, to be able to determine the reactional trend of the sympathetic nervous system by the evidence at hand. Such evidence is always present, oftentimes it is paramount, usually it is neglected in the mad desire to spot some absorbingly interesting local phenomenon. It should be part of the equipment of every gastrologist not only to recognize this evidence as a matter of routine, but also to place upon it its proper valuation, to adjust it scientifically to the general scheme. Its recognition should leap into consciousness coincidentally with that of organic imperfections, if for no other purpose than to curb impetuous judgment.

It is duly appreciated that in a field so comparatively new, many points are still under discussion, many questions still muted, many problems unsolved. Enough has been accomplished, however, to warrant the attempt to make practical that which has already been done. Such an attempt must of necessity be more or less schematic and apologies are offered in advance to anatomists, physiologists, and neurologists for any flaws in the evidence. The literature appended may be of service to those who wish to pursue the subject further. The main object here is to present it in as concise and practical a manner as possible, so that it may constitute a part of routine examination.

The visceral nervous system comprises that portion of the general nervous system which regulates those organic functions that are not under voluntary control. It is the sympathetic system of the older writers. In recent years it has been variously called the vegetative system or the autonomic system. The latter designation, however, is misleading in that it is especially reserved for a specific portion of the general sympathetic system. The whole sympathetic system then is primarily divided according to its functional activity into (1) the sympathetic system proper and (2) the autonomic system. These two subsystems are antagonistic in their directing influence upon the structures which they control in so far as they endeavor to establish a normal balance of function by respectively increased or diminished activity according to individual requirements at any given time.

The systematic system proper (called also the vertebral sympathetic) may be said to arise from the cervical, dorsal, and lumbar ganglia located on

each side of the spinal column. These are connected with the spinal cord from the second dorsal to the third or fourth lumbar segments by roots designated rami communicantes. The rami communicantes are composed of respectively white and gray fibers. The white fibers arise in the intermediolateral columns of the cord and emerge from the latter with the cerebrospinal nerve roots. These fibers are medullated. The gray fibers, which are non-medullated, arise in the ganglia themselves and pass back to join the cerebro-spinal nerves. By these two sets of fibers the sympathetic system is circularly joined to the central nervous system.

The course of the sympathetic fibers from the vertebral or lateral ganglia to the structures innervated is interrupted by a second system of ganglia, the colateral ganglia. Those of immediate interest in gastroenterology would be in order of descent from cervical region to pelvis, the superior and inferior cervical, stellate (upper three thoracic), celiac, or epigastric, superior and inferior mesenteric. As to the location of these, it will suffice to indicate here that the first three are situated close to the cervical vertebræ in relation with the sheaths of the internal carotid and superior intercostal arteries, the epigastric situated behind the stomach in front of the aorta, the superior and inferior mesenteric in near relation to the superior and inferior mesenteric arteries. The superior and inferior cervical and stellate ganglia interrupt those sympathetic fibers coming from the first and second dorsal roots. The epigastric and superior mesenteric interrupt the fibers from the remaining dorsal roots. Of these fibers those from the third to sixth roots constitute the major splanchnic nerve, while those from the remaining dorsal roots constitute the lesser splanchnic nerve. The inferior mesenteric ganglion interrupts the fibers from the lowest dorsal and the lumbar roots. Thus, any impulses passing either to or from the abdominal viscera must be interrupted by this system of ganglia. It is the determination of the possibility of this interruption which constitutes the crowning and masterful work of Langley. Its importance for physiological conception has been far reaching and has rendered the differentiation between sympathetic and autonomic systems possible.

The course of the sympathetic fibers from the colateral ganglia to the viscera which they control is an uninterrupted one. The immediate nature of the termination in the viscera themselves is still controversial. There may or may not be an intermediate myoneural substance interposed for purposes of chemical reaction to stimulation. Our interest here is limited to the gross anatomy, to that part of this which is directly concerned with the digestive functions. In this connection, it can be said that the fibers derived from the cervical ganglia supply the parotid, submaxillary and sublingual glands, also the involuntary muscles of the upper part of the esophagus. Fibers from the stellate ganglion supply the muscles of the heart. Fibers from the epigastric ganglia (solar plexus) supply the lower esophagus, cardiac sphincter, liver, and pancreas with their ducts, and the small intestines. These fibers also control the vasomotor apparatus of the stomach and intestines. Fibers from the superior and inferior mesenteric ganglia supply the colon and rectum.

The whole sympathetic structure then can, to a certain extent, for practical purposes, be visualized into a system with four stations. First, the central station, consisting of brain and spinal cord; second, the station consisting of the lateral or vertebral ganglia; third, the station consisting of the collateral ganglia; fourth, the terminal station in the viscera. Any impulse originating in the central station and passing peripherally to the terminal stations in the organs may be interrupted and diverted either in the lateral or collateral stations. Provided the central stimulus is powerful enough, there should be organic reaction from salivary glands to anal ring. That the impulses should be unevenly distributed, that one organ alone should be affected at times, may be due either to interruption as indicated, or to individual organic special susceptibility.

On the other hand, an impulse coming from the periphery need never reach the central station. It may be diverted either at the colateral or lateral stations. Thus, an impulse originating in the colon and reaching the stomach would pass first to the superior mesenteric ganglion, thence to the epigastric ganglion, from this to the stomach. In this case the circuit is a short one, the lateral ganglia remaining uninfluenced. The readiness with which colonic affections react upon the gastric secretions is hereby at least partially explained. This is especially important in the clinical consideration of the remote effects of such conditions as chronic appendicitis, ascending colonic stasis, etc. By means of the colateral ganglia all parts of the alimentary tract are so intimately connected that almost any reflex is possible, and the most surprising combination may result. A fair example would be the distant and yet distinct connection between hemorrhoidal pressure and abnormally increased gastric acid secretion.

Impulses from structures not directly connected with the alimentary tract must pass by a more circuitous route. Thus, a reflex from the genital organs to the stomach would be transmitted first to the inferior mesenteric ganglion, thence to the vertebral ganglia, from these by way of the major and minor splanchnic nerves to the coeliac ganglion and from the last directly to the stomach. Or, impulses from the gastrointestinal tract itself to other organs must pass through two or three stations at least. A reflex from the intestines to the heart encounters the collateral, vertebral, and stellate ganglia, in the order named. A reflex from the same source to the skin (Head's zones) would pass by way of the collateral and vertebral ganglia.

The importance of these conceptions, schematic as they are, must be evident to all. With a proper working knowledge of these routes, etiologically obscure local abnormalities of function will often be explained by tracing the same to some distant focal point of unsuspected importance. This is especially true if at the same time there exists a hyperexcitability of the sympathetic system together with a habit of life or occupation and an environment calculated to react unfavorably upon it. Common observation of the ordinary run of gastric cases must have revealed to any close observer that many phenomena are beyond explanation, except upon the basis of some influence beyond direct physical or chemical insult bearing upon the organ.

In a general way, it may be said that any influence which stimulates this system inhibits and depresses the secretary and motor activities of the gastrointestinal tract from mouth to anal ring. It places a uniform inhibition upon hyperactivity of all degrees and kinds. Assuming for purposes of

demonstration that this influence could be exerted uncontrolled and unopposed to its maximum extent, there would necessarily result a cessation of all secretion and motion, a general paralysis of the tract. On the other hand, any influence conducive toward depression of this system would have the effect of stimulation upon all secretory and motor function. Alimentary health depends upon a normal mean.

Given a state of hyperstimulation or hypersensitiveness to ordinary stimulation of the sympathetic system proper, what would be the effect upon the digestive tract? In this regard let us pose an extreme cast. Beginning with the mouth there would result cessation of secretion of all the salivary glands resulting in deficient ptyalin activity (the common dry mouth). Proceeding downward there would be paralysis of the muscular structures of the esophagus resulting in difficult deglutition, impaired passage of food, tendency to relaxation (idiopathic dilatation). The cardiac orifice of the stomach would be in a continuous state of relaxation (rumination), eructation, regurgitation, fictitious vomiting). The secretory and motor functions of the stomach would be in abeyance (subacidity, achylia, constitutional atony, atonic dilatation with all the attendant symptoms of bloating and pressure). The pyloric sphincter would be in a state of constant relaxation (pyloric insufficiency with back flow of bile and pancreatic secretion). Lack of tone in the common duct would result in a constant discharge of bile into the duodenum with increased absorption (urobilinurea). In the small intestines deficient secretory and motor activity would produce delayed passage and digestion of chyme (fermentation) flatulency, deficient absorption, general malnutrition). The whole large intestine would be atonic. In the ascending portion this would add to the difficulty of the up-hill work already incumbent upon this portion of the tract (increased churning, stasis, fermentation, and decomposition, autointoxication, possible pseudo-appendicitis, real chronic appendicitis). In the descending portion there would follow the usual train of symptoms of deficient evacuation (stasis, fecal impaction, possible mucous colitis, rectal pressure). As the vasomotor apparatus of the tract is under control of this system we should expect various circulatory disturbances, usually of the nature of constriction resulting in general or localized anemia (interference with return circulation causing hemorrhoids, general visceral anemia resulting in unequal blood distribution, head pressure symptoms, insomnia, vertigo).

While the above array of local conditions is but a schematization for purposes of demonstration, and that ordinarily such an extreme state of sympathetic stimulation cannot exist, it is evident that these conditions are encountered daily in routine gastrological work, either singly or in a certain combination. The object here is to emphasize the point, that in judging these conditions etiologically it is always necessary to be aware of this sympathetic factor, not especially as an immediate determinant, but as that influence which directs the development of the local conditions, once they have been started by either local relation or extrinsic causes. It is the ability to recognize the possibility of this sympathetic influence as an etiological factor which will guard against many false diagnoses. Hence, in casting about for the cause of any of these conditions in a given case, it is necessary to determine not only the immediate relationship producing the condition, but also to determine why in this particular individual the sequence of development should have assumed this particular trend. In other words, what is the directing influence in the constitutional composition of the individual which would cause the effects of local insult to assume this particular phase. The proper conception of the case and especially its treatment will depend upon this, and success will attend him who has the ability and patience to master the situation in its entirety.

Fortunately, we are in a position today to accomplish this with some assurance of success. The investigations in regard to the physiological activities of the vegetative nervous system have emancipated us from the old and vague conceptions of hysteria and neurasthenia. Except as generalization they have lost gastrological interest. We pass beyond these to the determination of the specific facts of the nervous system. The ability to connect the various signs and symptoms referable to the sympathetic system should form part of the equipment of every examiner. These signs and symptoms are present in most cases, and in most cases they are consistently neglected. To intelligently appreciate these phenomena involves at least some knowledge of the reactions dependent upon the sympathetic system. It is this practical aspect which interests us here.

Briefly stated, the essential facts would appear to be the following: the dominating native stimulant for the sympathetic system proper is adrenalin. The cells of the sympathetic ganglia are derived from the same embryological source as the adrenalin producing cells of the suprarenal capsules. It is possible to speak of a sympathico-chromaphil tissue. Chromaphil tissue is found in every ganglion, in the sympathetic plexuses, in the paraganglia of Kohn. Hence this tissue closely follows the sympathetic. It is found also in the kidney, prostate, and ovary. The normal quantity of adrenalin in the blood is one to one-hundred million parts. This quantity is essential to life. In a dilution of one to five-hundred million parts, it will experimentally arrest the rhythmic contractions of the involuntary muscles of the intestines. The normal tone of this system is maintained by the constant secretion of this substance into the circulating medium. Diminution of the normal quantity will result in muscular weakness, loss of tone of the blood vessels, contracted pupil, and bronzed skin (Addison's disease). Excess of the normal quantity produces constriction of all blood vessels, increased contractile force of the heart, dilated pupil, decreased gastrointestinal motility (Renaud's disease). The influences which increase or diminish the quantity of adrenalin in the blood are not well understood. Extirpation of the pancreas leads to excessive activity of the chromaphil system. Thyroid injection raises blood pressure and adrenalin excess is constantly present in Basedow's disease. It is very likely also that intense emotional disturbance acts as a stimulant to adrenalin secretion. Cannon demonstrated its increase in the blood of the vena cava near the liver under this condition. It has further been shown that the secretory nerves for adrenalin are incorporated in the splanchnics.

As our interest here is largely practical the employment of adrenalin as a diagnostic measure for the determination of sympathetic hypersensitiveness naturally suggests itself. It has so been used. Memmeter proposes the hypodermic injection of

0.0005 gram for this purpose. This quantity in the average case will produce pronounced symptoms of sympathetic stimulation. In cases of hypersensitive sympathetic systems 0.00015 gm. will give the same result. There is some dispute as to the point of attack, the sympathetic system itself or the subcortical brain centers. It is needless to say that the method should be used with caution and the consent of the patient obtained. It is more suitable for hospital work. If employed in general practice it should be done only under the closest supervision, and then only as a last resource to confirm other indications. In comparatively safe form it can be employed as the Loewi test, intense mydriasis following instillation of one drop of a one to one-thousand solution. Fortunately its use is not necessary in the average case as there are usually sufficient other physical signs to warrant a conclusion. These may be elicited without difficulty in the course of any routine examination. They can be roughly classified into cutaneous, circulatory, and organ manifestations.

As the whole vasomotor apparatus appears to be under the control of the sympathetic system proper, the cutaneous manifestations assume an important diagnostic significance, especially as they are easily observed. They are largely in the nature of constriction of the vessels. Thus we may have the frequent defective circulation in the extremities (cold and clammy hands and feet, mottling, red nose). In the sensory sphere there would be hyperesthesia, susceptibility to heat and cold, feeling of numbness, pins and needles so-called, and dead fingers. Other signs are deficiency of perspiration (excessively dry skin), perverse skin reaction (responsive to emotional shock by extreme pallor), excessive pilomotor reflex (goose-flesh), factitious urticaria.

Among the gross circulatory manifestations may be mentioned easily produced cardiac palpitation (paroxysmal tachycardia), a rapid, intermittent, irregular pulse, transitory high blood pressure, visible severe pulsation of the abdominal aorta, extreme contraction of all abdominal vasomotor structures resulting in head pressure sensations, momentary vertiginous attacks, tendencies to hemorrhage from exposed mucous surfaces (excessive nasal hemorrhage), fleeting congestion of the latter (susceptibility to nasal catarrh), extreme fullness of the hemorrhoidal vessels (bearing down sensation in the rectum, hemorrhoids), exaggerated circulatory disturbances of the climacterium.

Some of the phenomena connected with the organs have already been indicated. Of special interest to the gastrologist are the excessively dry mouth, an exaggerated gag reflex, extreme facility for the passage of the stomach tube, pronounced relaxation of the cardia resulting in excessive regurgitation, pyrosis, and persistent tasting of food after meals, excessive relaxation of the gastric musculature with easily induced succussion sounds or fictitious sensations of gas accumulation, a tendency to epigastric shock as a result of emotional disturbances, and hypersensitiveness to deep abdominal palpation (irritability of the sympathetic plexuses).

The various phenomena just enumerated may be present individually in almost any case. As such they have small value. Their importance lies in group presentation. The existence of one should lead to the search for others and, if others are found, to a correlation and systematization of all in order to determine their bearing upon immediate local conditions in the organs under examination. In other words, the search for these evidences should involuntarily form part of every routine examination. While the condition which has been given the name of sympathicotonia may be nonexistent in such distinct sense as this name would imply, enough evidence has been produced to warrant the assumption that the sympathetic system proper can possess at times a reactional sensibility which must and has an important influence, not only upon the production of local functional defects, but also—and this is most important—upon shaping their development along fixed lines. Whatever may be the differences of opinion as to details of operation in the local sphere, one fact stands forth undisputed, and that is that the sympathetic system proper is the great inhibitor of excessive functional visceral activity and, as such, its reactional trend should be established in every case. Ultimate decision as to points of differential diagnosis may well depend upon the correct recognition of a tendency in one direction or the other. Were the importance of such knowledge more thoroughly appreciated, it is safe to assume that many popular fads and fancies of diagnosis would find scant soil for development.

As the emotional life of the individual exerts such important influence upon all gastrointestinal activity, and as the impulses directing this activity operate in large measure through the splanchnics, a consideration of this phase of the subject demands some evaluation. There is present in every case of chronic dyspepsia such a strong affective tone, closely associated with daily life and habit, operative only through the sympathetic or autonomous nervous systems, that to neglect it may determine failure for treatment in advance. The resistance which the individual is able to offer to the oftentimes unavoidable psychic insults of his environment, will depend largely upon the stability and reactional trends of these two systems. One can even go further and state with some assurance that in the non-resistant individual the condition of these two systems will determine in advance the particular character and course of development of the local lesions, once they have been started. Hence it is that some inhibit excessive functional activity, others deficient functional activity, under precisely the same provocative circumstances. This has always been more or less of a gastrological mystery. To some extent at least it is cleared, and whatever may be the outcome of future investigations we are at present in a position to determine intelligently why in some cases certain results are as they are. Given the incidents of the daily life of the individual, given his psychological setting as to affectivity, given the reactional trend of his impulse conducting sympathetic system—we may be able to forge a chain of evidence bearing very directly upon diagnosis, prognosis, and treatment. This applies especially to the constant irritation of the lesser emotional states, those operating over long periods of time, it being well understood that great psychic shocks must necessarily always result in total cessation of functional activity at the time. It is in the domain of gastroenterology that the wear and tear of the continuous minor mental irritations count for much. Added to this there is the exceeding prevalence of the now well understood anxiety states. It will be suggested that these are not digestive conditions. They might just as well be so considered, for in the large majority of cases

there is a very decided functional reaction in the digestive organs. This fixes the attention of the individual. The days for imaginary pains are passed. Organic distress is real, whether it be imaginary or not, and must be dealt with as such. Very few people will acknowledge any nervous weakness. They resent the imputation because for such it always carries with it a suspicion of mental inferiority. This hurts their pride, wounds their vanity. Who has not seen the individual in whom at the merest suggestion of nervousness there is aroused an instant antagonism? Yet to the practised observer the whole surface of the body may actually present a map of unstable sympathetic equilibrium. Popular notions of nervousness and real pathological nervousness may be as far apart as the poles. That which the layman calls nervousness is very apt to be a simple physiological excess of spirits. It is true that within recent years a certain popular notion of neurasthenia has become ingrained. It has taken its place with malaria, uric acid, more recently blood pressure, and autointoxication. In the near future it probably will be goiter, due to the extensive exploitation of hyperthyroidism. One already finds the women regarding their necks critically. If the prevalent idea of neurasthenia could be made to contain the possibility of gastroenterological involvement, it would serve the purpose, at least, of making the individual receptive for rational treatment in this field. The great majority of the cases in our gastrological clinics are the indefinite cases with either hyper- or hypofunctional activity. Beyond this there is not much to be found. It is often very difficult to determine where the trouble started and what keeps it up. It is in these cases that the slightest sign, symptom, chance remark or hint will often make the diagnosis. These are not to be found, as a rule, by complicated and ingenious local explorations, but by a keen and thorough comprehension of the broader issues involved.

If the incidents of the daily life of the individual can have such a patent bearing upon the functional activity of the digestive tract, with all its evil portent, and if this influence can only be operative through the sympathetic, it would be natural to expect that there should exist some demonstrable anatomical connection between this system and the higher nerve centers. It must be admitted that anatomical efforts in this direction have been unavailing up to the present time, but the clinical evidence of such connection is not only strong but compelling. Of the centers themselves very little is known. From these, wherever they may be, the efferent impulses must pass by way of the intermediolateral tracts in the cord, the anterior dorsal roots, and white rami communicantes to the vertebral ganglia, thence to be distributed to the various viscera. Beyond this nothing is definite. As the spinal tracts, however, reach to the bulbar region of the cord, it is inconceivable that there should be no connection with the higher centers. The functions of the sweat glands, alimentary canal, and blood vessels may not be directly associated with cerebration, but there can be no doubt that they are under the influence of the emotions through the sympathetic. Anger, fear, shame, express themselves by pallor, blushing, perspiration, and tears. The impulses inducing these must pass by way of the basal ganglia. The distance of the latter from the cerebrum is short. On the other hand, afferent visceral sympathetic impulses cannot reach consciousness without cerebrospinal intervention. The route taken is often a circuitous one as in the case of Head's zones. The condition known as cenesthesia, in which consciousness is cognizant of the harmonious action of all the internal organs, is another illustration. Examples of psychic participation in disturbed functional activity could be multiplied indefinitely. They are the common property of every one. Why in so many individuals the stomach or intestines are the organs selected may be explained by what Hemmeter has designated "psychic facilitation by attention." That the attention itself should so often be directed to the stomach is a psychological problem. This organ stands very close to the individual's primitive instincts, and in its functional activity may very well interfere with contentment. Of all the organs, its behavior is most closely connected with consciousness. Hence it is that, through it, what the psychologists call free floating fear becomes operative. This commodity, as typified in the anxiety neuroses, is very widely distributed under present conditions of life, so that there need be small wonder at its potent influence in the causation and maintenance of stomach diseases. If it does not actually cause the disease, it constitutes a powerful factor in maintaining it, once it has been started. Given the proper mental conditions and almost any foodstuff will disagree at times, however harmless it may be in itself. This momentary disagreement can very well be perpetuated indefinitely by psychic attention which operates through the sympathetic. It would be an interesting clinical problem to determine whether in any such concrete instance, there does actually occur in the stomach a physicochemical disturbance.

In view of these indisputable clinical facts, it seems reasonable to assume that there must be an uninterrupted material connection between the sympathetic system proper and the highest brain centers through which alone consciousness can operate. The actual location of these whether, for example, in the hypothalamus or the pituitary body, on account of its close connection with the chromaffin system, is of minor practical importance. In line with these conceptions, attempts have been made to connect the postulated sympathicotonic disposition with certain concrete mental states. Such connection has been assumed to exist in melancholia during the menopause on account of the strong adrenalin reaction obtaining at this period, also in the self-depreciative phases of paranoia, and the variable manifestations of the anxiety states. In the writer's experience there is no direct relationship between the actual qualitative and quantitative characteristics of the gastric functions in any emotional state. A condition such as melancholia may produce hypo- or hyperacidity, depending entirely upon the reactional trend of the sympathetic system through which the mental state must operate. Hence, it would be unsafe to assume that because an individual may be suffering from a condition of general depression, he must necessarily present an analogous condition in his local functional activity. He will do so only provided the sympathetic system proper is in sufficient excess of excitation to control those functions.

Enough has been said to indicate that the time has passed when nervous manifestations in gastric disease may be regarded in the light of epiphenomena. The work done upon the whole sympathetic complex during the past decade has raised

these manifestations to the dignity of an integral part of gastroenterology. A working knowledge and appreciation of the anatomy, physiology and pharmacology of this system is eminently desirable. Its defects, if present, should leap to consciousness with the same alacrity as do local functional or organic changes. Having established the latter in every case by the proper physico-chemical methods, judgment as to causation should be suspended until this system has been completely investigated. In order to do this quickly in the course of any routine examination is merely a matter of training and habit. Watch the regular work upon the ordinary run of cases in any gastric clinic, and the neglect of this phase of the subject will be only too apparent. The most compelling evidence of unstable sympathetic equilibrium will fail of appreciation, if not of recognition, because the habit for such recognition is lacking, or begins and ends in the vague diagnosis of a neurosis.

It is to stimulate interest in this direction that the present article has been written. The schematic presentation has been conceived for purposes of demonstration. From present knowledge it would be unsafe to assume the existence of such a clinical entity as sympathicotonia. Nevertheless, the sympathetic proper part of the vegetative nervous system undoubtedly presents certain reactional characteristics, evidenced in clinical and pharmacological manifestations, which should be thoroughly mastered in order that they may be compared with the also distinct manifestations of the autonomous system for the purpose of determining the state of equilibrium of the whole vegetative organization. In casting about for the causes of a depressed functional activity in the alimentary canal, it will be necessary to thoroughly appreciate any defects in this system, in order that such findings may be compared with the prevalent assumption of congenital asthenia, defective metabolism, or definite neurosis. At best, these are but unsatisfactory generalizations. Stated in the broadest terms, the sympathetic system proper is the great inhibitor of gastrointestinal functional activity, and as such its importance cannot be underestimated in any case, for whatever may be the local findings, whether of hypo- or hyperactivity, the ultimate cause of these may be found to be either a constitutional increase or decrease of this inhibitory power, rendering the individual peculiarly susceptible to the unavoidable insults of his enforced existence.

SURGERY OF THE SEMINAL VESICLES:

REMARKS IN REPLY TO CRITICISMS.*

By EUGENE FULLER, M.D.,

NEW YORK CITY.

Coincident with the call of the Chairman of the Section inviting me to make some remarks on the surgery of the seminal vesicles, I received from the New England Branch of the American Urological Association its report of the symposium held under its auspices last February in Boston, devoted largely to the seminal vesicles. As numerous references in the papers read at that meeting and in the discussions, were made to my work, it has occurred to me that perhaps a few remarks in reply to the criticisms raised would be of interest to the section. Personally I am always glad to be criticised, and feel that those who criticise should be honored by a reply. It is only through criticism that one is able to determine how the profession has been impressed by one's efforts. There is, of course, a wide range of criticism. Some of it may be very much to the point and show a line of weakness in an author's work, while some may show that the one making the thrust is himself the vulnerable party.

The chief paper of the symposium was read by Dr. J. Bentley Squier of New York, the invited guest. Its title was "Indications for Operation on the Seminal Vesicles." From this paper, which was of much interest—and I take occasion here to thank Dr. Squier for the kind allusion therein made to my work—there occurs the following remark: "I believe one of the main reasons why surgery of these organs has remained undeveloped for so long a period has been largely due to the current opinion that the vesicles were of such difficult surgical access. One American surgeon has for the past ten years devoted a large amount of his time to surgery of these organs and has contributed much to the literature. He has apparently not aroused the interest of the profession proportionately to the importance of the subject. Needless to say I refer to the work of Dr. Eugene Fuller of New York."

I feel that Dr. Squier's remark is very true as to the current professional opinion regarding the surgical accessibility of the seminal vesicles. In fact I am rather inclined to go perhaps farther than he does, and to state that the surgery is in my opinion technical, requiring skill and practice before one can expect to become proficient. Few in the profession think it worth while to perfect themselves in a new procedure which requires much study and practice until they are, as it were, forced to do so by the consensus of professional opinion. Only until a comparatively recent period did more than a few attempt prostatectomy, and those few were then the objects of much adverse criticism from the great majority; but now apparently most genitourinary as well as general surgeons try prostatectomy, and one no longer hears the procedure condemned. Seminal vesiculotomy is more technical and difficult than prostatectomy, consequently it will go through a longer period of probation, as it were, than did prostatectomy, and when it is finally through its period of initiation far fewer will try it than do now try prostatectomy. Although I have worked for a considerable number of years on surgery of the seminal vesicles without, as Dr. Squier states, "having apparently aroused the interest of the profession proportionately to the importance of the subject," I do not feel in the least disheartened; for having had this deserted field in great measure to myself, I have in that time been able to relieve a very large number of patients, and after all it is the gratitude of those one has cured which lends the chief charm to professional life.

In this symposium Dr. J. Dellinger Barney of Boston read a paper from which I take the following quotation: "The rôle of the seminal vesicles in chronic infection of the genital tract and in certain types of arthritis was long ago demonstrated by Belfield and by Fuller. . . . It remained for Fuller to wade boldly into the perineum and attack under cover of darkness a foe which might far better be vanquished in the light." Although I have a high regard for Dr. Belfield and for what he has accomplished, the original demonstration that arthritis can be dependent on systemic absorption from infected seminal vesicles belongs to me alone, as well as does the fact that chronic urethral discharges are often dependent on chronic seminal vesiculitis. I suppose Dr. Barney felt that I ought not to go about alone without a chaperone. As for the latter part of the quotation, my mind after reading it instinctively reverted to the Æsop fable concerning the fox and the grapes. Any surgeon who wades into the perineum blindly, running amuck as it were, certainly invites disaster. That sort of work I have never done, as my results show and as Dr. Barney, for whose benefit I have carefully demonstrated the operative steps of my procedure, is fully aware. The operation, as I perform it, does depend to a considerable degree on the guidance afforded by a trained sense of touch. Such guidance is as certain and as accurate as that afforded by the eye. In fact much more accurate under certain conditions. Guyon used to remark that no one who could not see, as it were, with his fingers could be an efficient genito-urinary surgeon. The late Professor Henry J. Bigelow, one of the most distinguished surgeons this country has produced and to gainsay whose brilliant work on litholapaxy is even now in Boston considered little short of surgical heresy, developed his operation through a training of his sense of touch. I do not for a moment believe Dr. Barney would speak in connection with Bigelow's operation of "wading boldly into the bladder and attacking under cover of darkness a foe which might far better be vanquished in the light."

The following remarks of Dr. Hugh Cabot, of Boston, in connection with the discussion strike me as confusing and quite incomprehensible. They are as follows: "I believe that Dr. Fuller's operation has been unnecessarily radical and has frightened us." . . . "I have not believed that incision of these structures (the seminal vesicles) for the drainage of chronic suppuration was satisfactory. The condition of the patients is such that I have not thought it important to dodge the issue by a palliative operation. It seems to me their condition is so serious they are clearly entitled to an operation as radical as a removal of the vesicle. On the other hand, if we are to regard the radical operation as

*Read before the Section on Genito-Urinary Surgery of the Academy of Medicine, December 16, 1914.

appropriate to the acute cases, we must be prepared to go the distance; prepared to assure these patients of good results, and we must be prepared to advise them of certain sterility, which in comparatively young men is a serious business."

In the first place, what is there about my seminal vesiculotomy operation to frighten Dr. Cabot? I have to date performed the operation in excess of seven hundred times. This large number of operations has been attended by just one case of fatality, the fatal issue in that instance being superinduced by the coexistence of a chronic nephritis. Less than five per cent. of my cases have expressed any dissatisfaction with the operative result obtained. A surgeon frightened by such results must be too timid to be classed as such. So it must be that something aside from this has caused the fright. It may be that the operation has been attempted, that the dissection has gone wrong, the bowel or other part being opened or injured, and that the surgeon has thereby become himself frightened. That being the case, it hardly seems fair to saddle my operation with the fright. Or it may be that the term frightened is here used in the sense or having caused chagrin or discomfort. When any pioneer worker in a surgical specialty devises a technical operation which will free chronic and hitherto incurable sufferers, many of those coming for operation will have already been, as it were, the professional rounds. Such patients after being cured not unnaturally have little respect for the abilities of those who failed to relieve them, and their adverse criticisms naturally cause chagrin.

Dr. Cabot states that my operation is unnecessarily radical, and then in the next breath holds that drainage of the seminal vesicles, my procedure, is not radical enough and consequently advocates a far more radical and serious, besides being a disabilitating procedure, namely, the surgical removal of the seminal vesicles for the elimination of disease. Such an abrupt shift in argument I cannot follow. My results with drainage in a very large number of cases show that it is radical and curative if properly performed. If my writings are studied it will be found that my drainage operation is often performed to restore potency, and that it not only does not cause sterility but not infrequently results in virility in cases wherein previous to operation a sterile marriage had existed. Dr. Cabot mentions sterility as the only disagreeable result from his proposed otherwise radically curative operation of removal of the seminal vesicles. Although the unnecessary production of sterility would probably bar his procedure in the minds of many, still, had he made mention of another resulting effect, namely impotency, he would not in my humble opinion find a corporal's guard out of a regiment of sufferers who would submit to his operation. I never saw or heard of a person who expressed any gratitude toward a surgeon where impotency had seemed to him to have resulted from operation. In most instances such individuals are very vindictive when alluding to the surgeon in question. I feel very certain had my operative efforts been attended by such results, I would have been forced to quit the field and probably the country long ago. I have on the contrary cured through operation many cases of impotency where the loss of the function was due to a diseased condition of the seminal vesicles. Years ago in the barbaric age of gynecology ovaries were needlessly and wrongfully removed. No one does that now. With the picture before us of the misery which resulted from the ruthless removal of the ovaries, there is every reason why the genito-urinary surgeon should avoid a like pit-fall. The rule of surgery to-day is to conserve and not to needlessly destroy.

In conclusion I wish to say regarding my dissection in the performance of seminal vesiculotomy, that the muscular perineal body is not injured, neither are the rectal sphincter and its encircling blood vessels. In fact, the dissection is so bloodless that it is an exception to have to ligate a single vessel throughout the performance of the entire operation. The rectal function is not disturbed. Retention in the majority of cases is a post-operative feature, requiring the passage of a catheter often only once, and rarely for more than two or three times. There is no shock from the operation, and little more disturbance than the taking of the anesthetic would account for. Thus though the operation is technically more difficult than prostatectomy, its gravity is not to be compared with that procedure. Any operation which exposes the seminal vesicles to view would necessitate more disturbance of the muscular structure of the perineum, and consequently would be surgically a graver procedure.

252 Lexington Avenue.

WHAT DO WE MEAN BY "THE UNFIT"?*

By Robert T. Morris, M.D.,
New York.

The difference between the terms artificial selection and natural selection are after all like the difference between the terms spiritual and material, nothing more than conveniences in nomenclature for academic discussion. If nature instructs man to make artificial selection, he follows the plan of nature. Therefore, in making artificial selection, he is making natural selection of divine order.

We really march to the music of the grand diapason of nature's organ rather than to flute notes of individuals or of sects. Nature guides us, even though the heads of pins of our small personal affairs are held so closely before the eye that we cannot see nature as a grand whole.

When a family has stored up enough qualities to fill one member with genius, nature then burns him up in order to get his products, just as we wastefully smoke out a swarm of bees in order to get their honey.

A family is often proud when a genius appears in its midst. They should be sad rather, because it indicates beginning disintegration of the family. In response to a law of organic evolution the progeny of geniuses disappear commonly, or revert to primitive types, and have to begin the family all over again.

Curiously enough the word "descent" is used ambiguously by people who speak of descent from a famous ancestor. We note the word to be correctly applied by descendants of men who become great through activities that injured their health. We find children really descended, and in need of the doctor's care, much of the time.

The idea that remarkably fine parents will have remarkably fine children holds good only through the mean stages of development of a family. In the uncouth stage and in the decadent stage of a family, the child is not remarkably fine. At each end then

*Advance pages from a book entitled "Wayside Notes" to be published shortly by Doubleday Page & Company, New York.

of the cultural period of a family we have a parallel to what is found at each end of the cultural period of a nation or of a variety of plant.

It is the duty of sons of geniuses to look after their health very carefully and to avoid as far as possible trying to emulate their parents' example. People often mistake genius for strength when it may be weakness, allowing the mind to escape in excess at some point which other men would keep under control.

There is a careless tendency to blame the children of geniuses if they do not engage the thread of their screws in the social order sufficiently well to take them into good position. The situation is one calling for sympathy. The remittance man is a type; usually a good fellow, well-bred, knowing the refinements, but not trained to any useful occupation into which he can fit. As the social world develops day by day, he has no screw point or thread to engage in any definite hole in which he can remain fixed and moving in unison with the progressive world. He has not been trained to take the place that is to be vacated by his father, because the father by gradual and slow adaptation fitted himself into a position which would require similar experience on the part of a son for filling a similar position. The son having been furnished with comforts has learned no way for securing comforts. He often is handicapped by sensitized protoplasm, handed down to him by a father who has injured his own cells while obtaining and holding position—and this handicap is a long one. His good-fellowship, founded in freedom from responsibility, leads him into all the enjoyable companionship of good-fellowship, and that is far from work—far indeed from work. As a matter of fact, he has been admirably and systematically trained for elimination. Is it his fault? No! He represents the perfectly logical outcome of a system which is part of nature's plan for shedding the surplus. Are we not then to extend our sympathy? Indeed I have always had in the depths of my heart as great a pity for the remittance man as for the girl on the street. Are they not all human beings like ourselves, calling for our sympathy in their misery? We note great waste in the social shedding of the remittance man. He is often of aristocratic lineage or at least of lineage denoting capacity. The remittance man has knowledge of the graces, of the humanities, and theoretical knowledge at least of the essentials for sociability. He could play a little trick on nature if nature did not purposely obscure the way. If he were to dig in the ditch or actually carried the hod, and not take one cent that he did not earn with shovel or hod, he then would begin to cut a true thread on his screw, and to give it a point. The world would turn his screw rapidly enough toward a secure position, if he were able to face starvation by refusing to accept a cent not personally earned by himself.

Nature usually prevents the remittance man from doing this because she really planned to have him eliminated. She cramps him in the narrow V of Vanity, and tells him that honor consists in begging rather than in labor—in leaving unpaid bills, rather than developing a desire for meeting obligations like a good sport. Nature tells him that parents brought him into the world, and therefore they owe him a living. He understands this as meaning that they owe him money, when in fact they owe him theoretically nothing more than the physical gifts which they gave him to be used for developing personal earning capacity. Practically, however, we have to take as a parallel a hunting dog brought up in such a way that he is trained not to hunt. Under these circumstances the parents really do owe the remittance man money. They were at fault, and argument is confined to a question about the amount of money. That question is settled between individuals, or at least by one side. Theoretically they do not owe him money any more than the gardener is expected to hang pears on a tree. It is the gardener's responsibility, however, to train the tree which he has planted, and if the father and the gardener fail to train their respective charges, it is a fault to be sure—but one that is not to be remedied by hanging pears on a tree.

Ordinarily it is not a question of fault on either side, but is simply a response to nature's plan. I knew one remittance man, a fine wild fellow, whose source of income was absolutely cut off. He went to work in a factory at earning his own living, and told me that for the first time in his life he was really happy. He said further that he was prouder than he had ever been before, because he was doing what no one thought him capable of doing. Previously they had given him credit only for skilful construction of letters to his father, calling for money. Ordinarily the remittance man will not labor because of social pride, like a girl who refuses to do housework—preferring to become a prostitute. It is social pride that takes them both to where they find themselves.

The incentive to work in the case of a young man is usually punishment or reward. If he is born with money "reward" already at his disposal, nothing but fear of punishment is left for driving him into labor, as a rule. Experience soon teaches him that he need not worry greatly about punishment. Consequently, he fails to develop an appetite for work. The time will come when a system of pedagogy will take charge of this subject. It will show the youth certain things which are to be accomplished in natural science and which he probably cannot work out successfully. His vanity will then be aroused and turned to profitable account.

When Darwin presented his theory of the elimination of the unfit, many people who felt themselves to be targets became offended. When Osler said that the best constructive work was done by men under the age of forty, and jocosely added that men past sixty should be chloroformed, many who felt themselves to be targets were offended, but continued to live and to be busy nevertheless. Unfitness is a relative term and has application in relation to two separate and distinct utilities. The navel orange is unfit for survival in nature's plan, but is extremely valuable for man's uses. The man who could express the sentiment of Dorian Grey was unfit for survival in nature's plans, but was extremely valuable for cultivated man's uses. Before fitting the thorny crown of the word "unfit" to himself, a man must first stop to consider if he is not extremely valuable to his fellow men, even though he may not be destined for the survival of himself and his progeny in nature's plan.

616 Madison Avenue.

Pneumococcus Infection and Splenectomy.—U. Comelli performed this operation on rabbits into which he had injected pneumococci. He found that if the spleen is removed coincident with the beginning of the rise of the temperature, there would be a fall in the latter, but it would rise again during the terminal stages of the disease. If, however, the spleen is ablated after the temperature has risen, there is no recurrence of temperature following the fall.—*Il Policlinico.*

PROPHYLACTIC AND THERAPEUTIC IMMUNIZATION AGAINST TUBERCULOSIS; ITS POSSIBILITIES AND LIMITATIONS.

By SILVIO H. VON RUCK, M.D.,

ASHEVILLE, N. C.

When Sir A. E. Wright[1] wrote the epigram, as a motto for his "Studies on Immunization," "The Physician of the Future Will Be an Immunizator," he expressed a view which is shared, more or less exclusively, by most students and investigators of infectious diseases. In its practical aspect, however, the viewpoint of the clinician must be taken into consideration, who but rarely deals with conditions which are amenable to a comparatively simple procedure of immunization. In the struggle for existence, both macrocosmic and microcosmic, conditions are almost invariably complex, and, in disease processes which are manifestly dependent upon bacterial action, it is often difficult, if not impossible, to determine the particular microorganism which is responsible and which, in the form of a vaccine, may be employed as a means of immunization with the expectation of success. Yet, as soon as two or more of these vaccines are combined and administered with the hope of promoting a curative action, the field of positive teleological therapy is abandoned for that of empiricism.

If, however, we impute to Sir Almroth the view that the work of the physician of the future will be rather prophylactic than therapeutic, rather preventive than curative, then indeed the truth of his epigram will stand unchallenged, for it is in the prophylactic treatment of bacterial disease that immunization finds its most successful application.

Immunization against a bacterial disease is a process by which the organism is protected against the pathogenic action of the related bacterium, either by virtue of a successfully withstood attack of the disease or by the deliberate parenteral introduction of the bacterial substance, usually the virus itself in an attenuated form or in a form in which it is not capable of causing clinical disease. The result is a condition of hypersensitiveness by virtue of which the organism reacts more promptly to infection, with the formation of antibacterial substances which counteract the infection and prevent the infectious disease. The establishment of immunity by self-immunization, leading to recovery from disease and protecting against later attacks, has been observed clinically for centuries; the attempt to make use of the same principle for the purpose of prevention is likewise old and culminated in Edward Jenner's vaccination against smallpox. Since then, immunization has been made possible against a variety of diseases, notably rabies by Pasteur, against typhoid fever by Wright, against cholera and plague by Haffkine. Passive immunization, that is, the injection of serum from an actively immunized animal into the infected organism, has been proved highly useful in diseases with very short periods of incubation, *e. g.* diphtheria (v. Behring); tetanus, epidemic meningitis (Simon Flexner).

Prophylactic Immunization Against Tuberculosis.—In the case of prophylactic immunization against tuberculosis, the problem has presented many great difficulties which were not solved by the prophylactic vaccines, consisting of living tubercle bacilli, introduced for use in cattle by v. Behring, by Koch and Schuetz, Heymans, Klimmer, and others. In contrast to conditions in infection by other bacteria, where the virus is easily broken up by the tissue fluids and therefore promptly stimulates the formation of reaction-products, the tubercle bacillus is very resistant to the action of these fluids, and is known to persist in the clinically non-tuberculous organism for years. Yet, as Wright points out in the report on his researches on pneumonia in the Transvaal, before the organism can respond to the parenteral introduction of a vaccine, this must be disintegrated by the tissue fluids, and must be broken down. The injection of killed tubercle bacilli, with a view of securing an immunizing response, did not succeed because the dead bacilli were encapsulated in tubercles, in various organs, and failed to be absorbed. Attempts have been made to immunize human beings by means of living tubercle bacilli, either non-virulent or alleged to be so (F. F. Friedmann), or virulent but in minute numbers, from one organism up (Webb and Williams); but this mode of immunization, theoretically correct though it may be and in accordance with Koch's view that only the living tubercle bacillus could be depended upon to produce immunity, is too dangerous ever to gain any popularity.

It was therefore a distinct advance when Dr. Karl von Ruck[2] introduced a vaccine, for the purpose of prophylactic active immunization against tuberculosis, which contains all active constituents of the tubercle bacillus, chemically unaltered, in solution, and therefore in a form immediately available for absorption. He had for years successfully employed an extract containing the water-soluble substances of the tubercle bacillus, and had demonstrated the efficiency of this vaccine clinically and experimentally. With the introduction of his new vaccine, which also represents a complete antigen but is better balanced quantitatively, it became possible to produce a perfect immunity against the pathogenic action of the tubercle bacillus and to immunize normal persons against the disease.

It has been denied that it is possible to immunize normal animals and persons against the pathogenic action of the tubercle bacillus, because of the undisputed fact that immunity is dependent upon the sensitization of the organism by the virus against which it is engendered. This is maintained *e. g.* by P. H. Roemer[3] in an able discussion of the problems of specific hypersensitiveness and immunity to tuberculosis, by v. Pirquet[4] in his "Clinical Studies on Vaccination," and by other authors. It may be argued successfully that the introduction of a vaccine in solution, which contains all body substances of the tubercle bacillus and is, therefore, a complete antigen, is sufficient to produce the required sensitization of the organism; yet the question is, in human subjects, really an academic one, because it hardly ever happens, except in the case of very young children, that we find an organism which is entirely normal with respect to the tubercle bacillus. Post-mortem examinations and the application of the tuberculin tests in immense numbers of adults and children have shown that the infection of the human organism with the tubercle bacillus is practically a general one in all persons at the age of fourteen, and that, therefore, even healthy persons after that age are infected and sensitized. In other words, while they are not tuberculous, they are tuberculized, and any procedure undertaken with a view of immunizing them will build upon a certain degree of immunity which has already been acquired in consequence of the first infection.

Small children and infants also are often found to possess a degree of specific immunity, if they have been born of tuberculous mothers by whom the immunity is transmitted.[5] This immunity is perhaps not always lasting but will, in many instances, be sufficient to stimulate a prompt response to exogenic infection, when the infant or child is exposed to it. It may be mentioned in passing that it has actually been shown clinically[6] that a tuberculous heredity provides a somewhat better prognosis than a heredity free from tuberculosis. The various "scrofulous" stigmata of childhood also may be taken as symptoms of hypersensitiveness or as forms of relatively harmless disease by which immunity to tuberculosis is acquired; indeed v. Pirquet[4] has it that disease is but one stage in the production of immunity.

The prophylactic immunization against tuberculosis by means of a suitable antigen, such as the vaccine of Dr. Karl von Ruck, would therefore resolve itself, in many cases, in the stimulation of immunity, the basis for which has already been laid by an earlier infection.

There are, however, cases in which no family history of tuberculosis and no exposure to infection can be ascertained, in which there is no response to the tuberculin tests and all diagnostic laboratory tests are negative. That even these cases, in which the organism must be assumed to be normal, can be actively immunized by means of a proper antigen, is shown by our experience in at least four infants less than one month old, in whom the history was quite negative. Vaccination produced specific antibodies and bactericidal power in the serum of each one of them. One other normal child was immunized nine years ago, at the age of two, and the active immunity then produced still holds undiminished. Like experiences have been observed in experiment animals which were certainly not tuberculous and were successfully immunized with the vaccine.

Among 339 children who were treated with the vaccine,[2] and who had been subjected to careful clinical examination, including a search for enlarged lymph glands, physical signs in the lungs, the reaction to tuberculin tests, blood studies, and serum examinations before and after the administration of each dose, 85 had been found to be normal. In all of these normal children (as was the case in the suspect and the tuberculous individuals) the administration of the vaccine was followed by the appearance of complement-fixing substances in the serum; the blood alkalinity was increased from an average of 0.86 to one of 1.20 per cent.; the agglutinins, which had been present in only a few of these normal children in serum dilutions of 1:5 or 1:10, had increased to 1:100 from three to eight months after treatment.

This demonstration, which was also supported by animal experiments, that it is possible to stimulate the normal organism to the production of specific antibodies by treatment with a complete antigen in solution, should dispose of the view that only that organism can be immunized against the tubercle bacillus which is sensitized by an infection, *i.e.* by the living virus. This latter view is not justified by experience in smallpox, where the organism is "new" to the virus and yet elaborates specific reaction products in response to vaccination; nor is it justified by experience in typhoid fever against which immunization of the normal organism is done successfully, even by the killed virus. It is finally contradicted by the mechanism of autoimmunization in response to the first infection with tubercle bacilli, in which the normal organism acquires the power of forming antibodies.

The accepted prophylaxis against smallpox consists in the specific immunization against the smallpox virus by means of vaccination of all children before they are permitted to enter school. The immunity resulting from this vaccination is commonly accepted as lasting for a space of about seven years, after which revaccination should be practised. The results of this mode of prophylaxis are particularly obvious in the German army, as compared with the Austrian, French, and Italian armies, vaccination not being compulsory in the three latter as it is in the first. Simon[7] cites the following figures:

Army	Period	Per Annum			
		Morbidity	Average	Deaths	Average
German	1875–1892	13	0.7	1	0.05
Austrian	1875–1886	9864	896.7	595	54.0
French	1875–1892	8356	491.5	705	41.4
Italian	1875–1894	2565	135.0	193	10.1

The success of specific prophylactic immunization against typhoid fever in the Boer war and in our own experience in the U. S. army is present-day history and should hardly need proof. Suffice it to quote, also from Simon,[7] that in our concentration camps at the time of the Spanish war, in a body of 10,759 men, there were 1,729 cases of certain typhoid fever and 964 cases of probable typhoid fever, together 2,693; that is, 25.03 per cent. morbidity, with 248 deaths, or 9.2 per cent. of the morbidity. On the other hand, among the 12,801 men who were concentrated in 1911 at the maneuver camp at San Antonio, all of whom had been vaccinated either before their arrival or as soon thereafter as possible, there developed but a single very mild case, in a private who had not completed his immunization. During the same time period, there were reported in the city of San Antonio, 49 cases with 19 (38.7 per cent.) deaths.

The difference between these acute infectious diseases and the essentially chronic tuberculosis is one of degre only in so far as the question of prophylaxis is concerned. In both classes an immunity is developed in response to the sensitization of the organism with the bacterial substances, and in both classes the immunity affords protection against later infection, and prevents disease. The conclusion is obvious, that the logical method of preventing tuberculosis would be a general specific immunization, the same as it is practised against smallpox. Simon[7] says that, if the incubation period of a given malady is sufficiently long so as to permit of the active mobilization of the defensive forces before symptoms of disease actually develop, attempts at active immunization would, of course, be indicated. Chronic infections further would, theoretically at least, lend themselves to treatment of this order.

Hitherto the efforts of the world-wide crusade against tuberculosis as a disease of the masses consisted in ascertaining, and, as far as possible, rendering innocuous the sources of infection; in teaching tuberculous persons how to avoid infecting others, and in raising the general resistance, the "first line of defense" as it has been aptly called, against infection. Unfortunately all this is entirely inadequate to cope with the problem, the more so

as it is quite impossible to eliminate all possible sources of infection. This being the case, it remains as the only logical conclusion to be drawn that only specific immunization against tuberculosis can be expected to produce efficient results and to lower the morbidity and, eventually, the mortality of tuberculosis. This method of procedure would be the more reasonable because it would avoid the ultimate raising of a generation which is "new" to the tubercle bacillus and which would be absolutely defenseless against a sporadic infection; it would rather result in a tuberculosis-fast generation and would hasten the solution of the tuberculosis problem by centuries, in the same manner in which vaccination has solved the smallpox problem in less than a century.

Therapeutic Immunization.—"The treatment of tuberculosis stands in the sign of the theory of immunity," is the pithy manner in which van Calcar expresses himself in the introduction of his treatise on tuberculosis and immunity,[7] and it may be truly said that the treatment of tuberculosis is gradually, but none the less surely, developing in the direction of the means which nature employs for its arrestment and cure in those cases in which the disease either never becomes clinically manifest or in which it is recognized in a very early and uncomplicated stage and yields promptly to the so-called general methods of treatment, by climatic, hygienic, and dietetic measures.

It will be well to realize that these general measures are actually only a means to the end, that they do not accomplish the arrestment of tuberculous disease directly, but that they act indirectly by enabling the tuberculous organism to develop a sufficient degree of specific, antituberculous immunity to prevent the further multiplication of tubercle bacilli and the extension and dissemination of the tuberculous process. Under favorable conditions the body responds to the invasion of tubercle bacilli by removing or by destroying them before they have had time to exert their pathogenic action and to lead to tubercle formation which is, in itself, a form of defense of the organism, tending to localize and circumscribe the infection. If tubercles have been formed, they cause a connective tissue proliferation that is often sufficient to encapsulate them, and to exclude them from the circulation, making an extension of the tuberculous process by contiguity or by way of the circulation impossible and resulting in a latent or quiescent focus which, by becoming cretaceous or calcareous, in most cases loses much (although not necessarily all) of its infectivity. As far as tubercle bacilli have been absorbed in the circulation and have been destroyed, the resulting toxic products of bacteriolysis (endotoxins) are promptly neutralized and rendered harmless. This occurs in cases which may never present clinical symptoms of tuberculous disease.

The process of defense which is thus set in motion by the organism, under favorable conditions, becomes active in the first instance because of a sufficient natural resistance by which the invasion of large numbers of tubercle bacilli is prevented. The power of destroying the bacilli and of neutralizing their toxic products, however, depends upon the ability of the organism to respond to the bacillary irritation by the formation of specific protective substances which, when they are present in sufficient amounts, render the blood capable of destroying the virulence of the microorganisms, and antitoxic in so far as the endotoxins require neutralization; in other words, it depends upon a specific resistance or immunity.

The natural and the specific resistance of the organism are both exerted in the majority of cases of tuberculous infection; for, while practically everybody is subject to infection with the tubercle bacillus at some period or another, by the time the age of puberty is reached, only about 20 or 30 per cent. of all living show evidences of active tuberculous disease, *i.e.* evidences that the resistance was broken through; even then it becomes active again and a restoration to health becomes possible, for only about 10 per cent. of all deaths are due to tuberculosis.

In those instances in which the natural defenses were not capable of preventing a massive infection, and in which the organism failed to respond to it by developing an adequate specific resistance, where, in consequence of this deficient resistance, active tuberculosis has occurred, the question arises of increasing the resisting power of the organism, and then of stimulating its power of repair so as to, first, limit and arrest the tuberculous process and, then, cause its retrogression and healing. As we have seen, in many relatively early cases this can be accomplished by general methods by which the body is placed at rest and under the most favorable conditions of nutrition, so that its specific resistance, which presumably was insufficient owing to weakening influences like poor nutrition, unfavorable surroundings, overwork, etc., shall be increased and rendered capable of accomplishing the object sought. This result is illustrated in those early cases of tuberculosis in which the disease is recognized before its destructive stage has been reached and before it has exerted any deleterious effect upon the functioning power of the vital organs. In these, the general methods of treatment are frequently successful in improving the impaired nutrition and promoting the establishment of a specific resistance in a satisfactory degree.

Unfortunately this desirable result is, all too often, not obtained. Whether the disease has progressed too far for nature to arrest it without artificial aid, or whether other organs than the one primarily affected are incapable of normal function, whether intercurrent diseases tend to weaken the organism or whether it is not possible to induce and maintain ideal conditions under which nature could accomplish a cure; all this will have to be decided for each individual case. At any rate, very often nature does not prove herself an efficient physician and requires suitable assistance, for without it the tuberculous process would extend and progress toward the destructive stage. In such cases specific treatment offers the only effective means of arresting the tuberculous process, provided, of course, that the latter has not yet advanced too far in the phthisical stage and that the patient is not unduly weakened by fever and by toxemia.

It is unfortunate that, since the discovery of the tubercle bacillus, the term tuberculosis has been used unqualifiedly for all stages of the disease-processes for which the bacillus is directly or indirectly responsible, and that, not only in the minds of the laity but also in the minds of many physicians, it is synonymous and identical with phthisis or consumption. Before the days of bacteriology, which gave to the term tuberculosis an etiological significance, it had been pathological or descriptive, having been introduced by Schoenlein[8] to designate those affections for which the tubercle is the char-

acteristic anatomical lesion. Schoenlein differentiated sharply between tuberculous phthisis and other forms of consumption. With the recognition, however, of the fact that phthisis represents in the vast majority of cases the destructive and terminal stage of tuberculosis, the latter term was employed more and more, especially since the tubercle bacillus had been demonstrated as the cause of tuberculous disease.

The fact must not be lost sight of that something more is required in the genesis of phthisis than the tubercle bacillus, and that not every tubercle formation leads to consumption. The factors which may be responsible for such an outcome are manifold and have been comprised under the convenient term of predisposing causes. Yet we must not confound predisposition to tuberculosis with predisposition to phthisis. Tubercle formation follows almost invariably upon infection with the tubercle bacillus (leaving out of consideration the finding of "latent" tubercle bacilli without the characteristic lesions, as they have been studied especially by Bartel and Neumann—cf. K. v. Ruck[10]), if the bacillus succeeds in breaking through the first lines of defense and in passing through the skin and mucous membrane; but in the resistant organism the tubercle formation does not progress and does not lead to phthisis, the predisposition for it being absent. Tuberculosis in its uncomplicated form has a tendency to localization and to healing. When, however, the tuberculous lesion undergoes cascation and softening, *i.e.* when phthisis supervenes, the tendency to extension exists, in part because the process becomes complicated by mixed infection through which the destruction of tissue is encouraged and hastened, and because of the liberation and absorption of products of virulent tubercle bacilli, since the transition of "antigen" into the circulation tends to disseminate the infectious process.

It is evident, therefore, that the treatment of phthisis presents a far more difficult problem than that of uncomplicated tuberculosis. In fact, while the latter will yield to a specific remedy which stimulates the formation of all required antibodies, an active immunization does not usually suffice in phthisis.

The etiological or vaccine treatment of infectious diseases being specific and applied by means of the causal virus of the disease, the necessity that this latter be definitely determined is naturally a condition of success. In diseases in which the bacterial causes are multiple, the problem becomes more difficult because of the uncertainty regarding the relative importance of the various bacteria that are involved in the process or that are simply found as contaminations. Multiple vaccines are frequently used in the hope of overcoming thereby the results of multiple infection.

Ordinarily the cases of tuberculosis that present themselves for treatment are actually phthisical, and the clinical diagnosis of incipient tuberculosis is, in the majority of cases, a euphemism for incipient phthisis. This is an unfortunate consequence of the demonstration that the phthisical process almost always depends upon a tuberculous basis, and of the custom before mentioned of employing the terms tuberculosis and phthisis as interchangeable. Therefore, if we say that tuberculosis is communicable and preventable, this must not be applied to phthisis without qualification. The curability of tuberculosis should be insisted upon with the proviso that it comprises the uncomplicated and relatively early forms of the disease, and it should be understood that the advanced forms are by no means as easy to treat as the public has been taught to believe.

A phthisical process being a very complicated one its turberculous basis is only one of the many phases to be considered. In addition to it there is not only the complicating secondary infection which tends to hasten and to aggravate the destructive process, but there is also this process itself, the pathological lesion which impairs the functioning power of the affected organ; further, there is the extension of the process, either by continuity or contiguity, or by way of the circulation, through which new areas, hitherto normal, are involved in the disease; and finally there is the deleterious effect of the disease upon the general condition of the patient to be considered, because of which pulmonary consumption has been defined as a disease of all parts of the body (Richard Morton[11]). In all cases of tuberculous disease the treatment must take account of several aspects; it must be directed against the infection and also against the pathological process; it must further benefit or relieve the associated pathological conditions and the sequels engendered by the disease.

It is only the infection itself which can be influenced directly by specific treatment. By stimulating the specific immunity reaction of the organism, it can, in favorable cases, promote the arrestment of the tuberculous process, by securing the destruction of the infectious organisms. It can also relieve the body of the intoxication following the breaking up of the bacilli. It is, however, powerless directly to affect the pathological process itself or to induce its retrogression and healing. This depends upon the ability of the body cells to undertake the necessary reparative function and this in turn depends upon various factors among which are of primary importance the nutrition of the body and the extent of the pathological lesions. In the presence of mixed infection, especially by pyogenic bacteria, the arrestment of their deleterious activity also forms an important phase of treatment and one which, if it fails, may render the specific antituberculous immunization unavailing.

It is undoubtedly due to the multiple aspect of phthisis in its manifold clinical phases that so many different remedies have been advocated for its treatment while, since the etiology of the disease has been established, therapeutic endeavor has often been unduly restricted to its bacterial nature, except, indeed, in the case of the dominant general methods of treatment, which deliberately attempt to strengthen and restore the entire organism and all its vital functions. Nor are these general methods of treatment ever undervalued even by the most enthusiastic supporters of specific therapy; for, as was pointed out editorially in the *Journal of Tuberculosis* some years ago:[12] "there is no remedy for tuberculosis, nor will there ever be one, no matter how specific, that acts or will act in the absence of suitable conditions of hygiene and diet." The necessity of these general methods is therefore not questioned and it is even conceded that the scope of specific treatment is limited. In its beneficent working, however, the latter tends not only to arrest the further multiplication of tubercle bacilli and to lessen the absorption of toxic substances, but it also is excellently calculated to break up, by this action, the many vicious circles which are of such

immense and fateful clinical importance in the management of phthisis, as has been set forth clearly by Dr. Jamieson B. Hurry.[13]

The manifold aspect of phthisis or of clinical tuberculosis further renders it impossible that there ever should or could be offered a specific remedy for the treatment of tuberculous disease which could be designated as *the* tuberculosis cure κατ' ἐξοχήν and to which all cases of tuberculous disease could be expected to yield promptly. Such a remedy is possible and exists only for uncomplicated tuberculosis. It is not possible for advanced cases of the clinical disease or phthisis; that is, tuberculosis plus a variety of pathological conditions occurring in consequence of tuberculosis, and complicating it.

One may, therefore, never hope to cure a well established case of phthisis solely by periodical injections of a tuberculin or of an antituberculosis vaccine. The possibilties of the action of the latter will always be limited by the sums total of the clinical assets and liabilities of each individual case. In instances where considerable destruction of lung tissue has taken place and where the breaking down of a caseous focus causes a constant absorption of antigen and, therefore, a constant pyrexia; where the digestive organs are involved and the nutrition is greatly impaired, the administration of any vaccine, with the expectation of a clinical cure, would almost certainly be doomed to disappointment, unless steps had been taken to control the fever and to improve the nutrition. Where, however, the tuberculous focus is circumscribed and not very progressive, where digestion and elimination are good and the nutrition is satisfactory, where the temperature does not rise above normal or only slightly so, specific treatment with a suitable vaccine bids fair to arrest the tuberculous process within a relatively short time, after which the process of repair will be activated and become productive automatically.

In the ordinary run of cases of phthisis, as they are met with in private practice, in the clinic, and in sanatoria, the adoption of specific remedies can never render the other methods superfluous. It supplies an ancillary method of treatment which exerts its action against the underlying cause of the phthisis. Specific remedies must be considered as useful and valuable, even as indispensable aids in the management of these cases, but they must not be looked upon as the be-all and end-all of treatment; they must not be permitted to encourage carelessness or want of attention to the general factors and requirements of each individual case.

A NEW AND GREATLY SIMPLIFIED METHOD OF BLOOD TRANSFUSION.

A PRELIMINARY REPORT.

By RICHARD LEWISOHN, M.D.,

NEW YORK.

THE question as to the best method of transfusion of blood is still an open one. The method of vein-to-vein anastomosis has in the past two years encroached upon the original Carrel method of uniting the artery of the donor to the vein of the recipient. These methods, however, have recently been almost entirely replaced by Lindeman's syringe-cannula method, which has the advantage not only of being much simpler technically, but at the same time of giving an opportunity of accurately determining the amount of blood transfused. Even Lindeman's method, however, is far from being simple. Its proper application demands a staff of four people, each one trained for this special work. Further the method is quite an expensive one on account of frequent breakage of the syringes. The method is apt to prove a failure if not carried out with great precision and rapidity, for the blood is apt to clot in the syringes. These facts limit its usefulness and restrict its general application.

There can be no doubt that blood transfusion can only be popular if it can be done by any physician without the necessity of acquiring special skill for the work; in other words blood transfusion ought to be as simple as any ordinary saline infusion.

What is the reason that all the methods heretofore applied in blood transfusion are so complicated? Why has it not been possible so far to have a method of blood transfusion as simple as an ordinary infusion? The only reason is the rapidity with which the blood clots outside of the body, namely in from three to five minutes. If it were possible to retard the rapid coagulation of the blood, transfusion could be performed with the greatest ease and without acquiring any special technique. Then all the complicated methods which we have used heretofore could be dispensed with.

Many different drugs have been applied in experimental physiology to retard or prevent the coagulation of the blood. The best known among them are the leech extract (hirudin) and sodium citrate and oxalate. I started my experiments with hirudin, but found that this drug if given in sufficient quantity to prevent clotting is so toxic that its applicability for transfusion is out of the question.

Sodium citrate, on the other hand, with which I have experimented during the last few months, has proven to be a most satisfactory drug for our purpose. I do not want to enter here into any detailed statements as to its anticoagulant action, as the chemical action of sodium citrate on the blood is well known.

I performed a series of experiments to answer the three following questions:

(1) What is the smallest dose of sodium citrate required to keep the blood from clotting for twenty to thirty minutes?

(2) Is the coagulation time of the blood of the recipient retarded? If so, its general use in blood transfusion would necessarily be greatly impaired (purpura, hemophilia, etc.) and

(3) Is it toxic in the amounts necessary for our purpose?

As this is only a preliminary report I shall refrain from giving detailed data about all my experiments and only state the most important results in the very briefest terms.

1. The amount of sodium citrate necessary for our purpose is very small, only 0.2 per cent. The blood was tested in ordinary test tubes. In these experiments ten cubic centimeters of dog's blood was added to different amounts of a 10 per cent. sodium citrate solution. If one takes 0.1 cubic centimeter of this solution and adds ten cubic centimeters of blood to it, the coagulation time is not changed compared to normal blood (both about five minutes). All the other test tubes, however, running from 0.2 upwards to 1.0, did not clot at all (observation time over forty-eight hours). From this experiment, which was repeated several times with exactly the same results, it follows that sodium citrate must be added at the ratio of 0.2 per cent. for the purpose above mentioned. The identical results were obtained with human blood.

2. The tests of the coagulation time after the introduction of the sodium citrate-blood mixture show that the coagulation time in the whole blood volume of the body is not only not retarded, but actually hastened, at least immediately after the transfusion. The normal blood taken from the carotid artery of the dog, before the experiment was started, showed five minute coagulation time. Three hundred cubic centimeters of blood were then removed from the artery, mixed with five cubic centimeters of 10 per cent. sodium citrate solution and then reintroduced into the jugular vein of the same dog. Three specimens of blood taken from the carotid artery at intervals of three minutes after injection of the blood into the jugular vein showed that the blood clotted in ten seconds. I shall not enter into the interesting aspects of this fact and only record it here. That much certainly follows from this series of experiments that there is no retardation of the coagulation time on account of the added sodium citrate.

3. The dogs showed absolutely no ill effects from these small doses of sodium citrate, as was to be expected.

I used for the transfusions the simplest outfit imaginable. I did not use large syringes, because they are expensive, break easily, and are entirely unnecessary for our purpose. The technique used is the following: I simply allowed the blood to run through an ordinary cannula into a glass jar, containing five cubic centimeters of 10 per cent. sodium citrate solution. While the blood was running into the jar it was stirred with a glass rod to effect a good mixture of blood and citrate solution. The blood was then poured into an ordinary glass funnel, which was connected with the other cannula by a piece of rubber tubing. The whole procedure took about five minutes.

I have used the method on two patients (transfusions of 300 c.c. and 500 c.c. respectively) without any untoward symptoms.

I would like to draw attention to a paper by Hustin of Brussels (*Annales et Bulletin de la Société Royale des Sciences Médicales*, May, 1914) which came to my notice when my work was practically finished. He used in one case a citrate solution mixed with glucose.

While the experimental part of this work was still under way, Dr. R. Weil reported at a meeting of the Academy of Medicine (December 17, 1914,) that he had used sodium citrate successfully in the wards of the General Memorial Hospital. He stated that the coagulation time is hastened after the injection of sodium citrate, a statement which I confirmed in my experiments.

I feel assured that this method will popularize transfusion very markedly as it can easily be applied by any physician without any assistance and without the haste and technical skill necessary for the proper execution of the older methods.

I wish to acknowledge my indebtedness to Dr. Baehr and Dr. Epstein for their valuable assistance in this work. The experimental work was done at the Pathological Laboratory of Mount Sinai Hospital.

MYOCARDIAL CHANGES FOLLOWING THE ACUTE INFECTIOUS FEVERS.*

By WM. A. DICKEY, A.M., M.D.,
TOLEDO, OHIO.

In the treatment of acute fevers, the internist is confronted with a many-sided problem. He must think not only of the treatment of the disease *per se*, but also of the pathological changes brought about by the infective agency in the different organs and tissues of the body, for these have a wonderful influence on the final result. They not only influence the prognosis, but have an important bearing on the line of treatment. The integrity of certain structures is of paramount importance, because upon their functional activity often hangs ultimate result. Of all organs in the body that need most careful watching in infectious diseases, the heart is the most important. It demands the most circumspect attention and discrimination on the part of the medical attendant. Certain processes of a more or less permanent character may be implanted during the progress of one of these diseases, leading to the sudden and unexpected death of the patient, to the discomfiture of the physician, and the inexpressible grief of the family. Death may take place not only during the height of the infective process, but suddenly after an apparent cure. Indeed, so profound may be the toxemic process from the very outset, that the cardiac involvement may overshadow all other phenomena in the symptom complex. And yet it must in truth be said that an already damaged heart may pass through an attack of pneumonia or typhoid fever, for example, without showing that degree of injury or embarrassment one would expect; so that we have no hard or fast rules to govern us. But I repeat that in all infectious diseases the heart must receive the most constant and watchful care.

Another matter of vital consequence confronts us, and that is vasomotor paralysis, the result of the action of toxins on the vasomotor center in the medulla; the maximum influence being felt in the splanchnic area, in this way destroying the normal equilibrium between the different organs and parts of the body. To this, however, I shall refer again. The anatomical arrangement of the heart as well as its dynamic requirements make it an organ of special care and attention in infectious conditions.

*Read at a meeting of the Northwestern Ohio Medical Association at Tiffin, O., October 21, 1914.

In adult life it is difficult to consider diseases of the heart without at the same time taking into consideration diseases of the blood-vessels. In childhood, this does not obtain to the same degree, if it does at all. And yet many of the diseased conditions found in adult life have their inception in child life. In childhood, the pericardium and endocardium do not suffer to the same degree that the myocardium does, and yet the infections cripple more or less every part of the heart. There is hardly a single infectious disease that does not affect the heart injuriously, especially the myocardium. More especially is this true in those cases characterized by marked sepsis. In the exanthemata, even the mild or moderately severe ones, marked changes are often found, and the more severe the infection, the more grave the myocardial changes. In scarlet fever, particularly the cases marked by severe sepsis, the myocardial degeneration is more marked than the endocardial. This is equally true of typhoid fever. Indeed in my own experience, the endocardial change in this disease is not as common as the myocardial. In those cases of typhoid complicated with peritonitis, the myocardial changes are relatively common and constitute a grave source of danger. In the more malignant forms of pneumonia, myocardial degeneration is very liable to occur, and the sudden death that takes place when any attempt on the part of the patient to make the slightest physical exertion unaided, even to sit up in bed, is due to this change. For this reason, I never make a prolonged examination of the posterior chest wall, after the initial one, unless some clinical symptom arises denoting a fresh invasion of new lung tissue, or some complication makes such an examination imperative. In not a few of the pneumonic cases that fail to rally after the crisis is reached this result is directly attributable to the weakened condition of the heart muscle, because of the overwhelming influence of the bacteriemia. Indeed, I think it is the well-nigh universal experience of all physicians that few diseases to which flesh is heir place such a heavy burden on the heart as pneumonia.

It is not so much the amount or extent of the pneumonic involvement that produces the fatal result in a given case of pneumonia as it is the toxemia acting on the heart and vascular system. It is true, however, that the blood must be sufficiently aerated to have something near its normal supply of oxygen or the nutrition of the cardiac muscle suffers greatly. In a paper entitled "The Heart in Pneumonia," read before the Section on Practice of Medicine at the recent meeting of the American Medical Association, by Robert N. Wilson of Philadelphia, he says: "The less perfect the aeration of the blood in its passage through the pulmonary tissue, the more positive is the deprivation of the cardiac structure of its proper supply of nutriment." Physiologists say that the blood in passing through the lungs must receive more than 90 per cent. saturation with natural oxygen in order to maintain normal nutrition. In the article already referred to Wilson says: "The more complete the stoppage of the blood and lymph streams in their course through the walls of the air vesicles, the more real is the mechanical overload thrown on the pulmonic valves and soon on a toxemic tired right ventricular wall." Thus it will be seen, speaking abstractly, the greater the amount of consolidated lung tissue, the more is the cardiac musculature sure to suffer.

As a result, we have often, early in the disease, dyspnea, weak, rapid, irregular pulse, diminished first sound with a well-nigh absent pulmonic second sound, blue lips and finger tips, with an increase in the area of cardiac dullness to the right of the sternum, and diminished blood pressure. In this type of pneumonia, we very frequently have such complications as meningitis, pleurisy ending in empyema, pulmonary abscesses, and other conditions, showing a general pneumococcic septicemia. This is not due to the high fever, as was taught by Liebermeister and others of his co-workers, but to the toxemia as well as the lack of oxygen. Clinically we see evidences of cardiac dilatation, and consequent incompetency with thinning of both ventricular walls and insufficiency of mitral and tricuspid valves, due, as Wilson says, to an acute diffuse myocarditis with cloudy swelling of the cells, often with fragmentation of the muscle fibers. He further states that "here and there are found areas showing extensive round cell infiltration, mainly of the interstitial substance between the fibers." In left-sided pneumonia or pleurisy, we may have a pericarditis from contiguity of surface, which sometimes results in an effusion into the sac or a local mural myocarditis, or both, which cripples the heart greatly. The mortality list in these cases is greatly augmented by reason of the fact that some part of the cardiac mechanism had been previously diseased, a fact to which I have already alluded; the lesion is not always the same, of course, as it depends somewhat on the nature of the infection and its degree of virulence.

In diphtheria, the myocardium is more frequently involved than either the endocardium or the pericardium, and the extreme probability of this occurring should always be kept in mind, and put the physician on his guard. The enervation of the heart in this disease is of rather frequent occurrence, and toxic or infectious bradycardia is seen very often; when the heart is rapid and gallop rhythm makes its appearance with a sudden drop in the number of beats, we are justified in considering these ominous signs and in acting accordingly. I have already spoken of the injurious influence of certain toxins on the vasomotor center in the medulla, by which the coats of the blood-vessels are paralyzed and an undue amount of blood is collected in certain areas, particularly the splanchnic. In no disease is this so liable to occur as in diphtheria; as a result the heart beats rapidly and irregularly, and finally ceases because of a lack of blood to contract upon.

In acute articular rheumatism, few cases fail to show some degree of cardiac injury; especially is this true in children if preceded or accompanied by tonsillitis. Indeed, we not infrequently see cases in which cardiac symptoms indicate the approaching rheumatic syndrome. I think I am safe in saying that 50 per cent. of all cases of rheumatism show permanent evidence of heart disease; the other half are cured by judicious, well-directed treatment. Children under ten years of age reveal the largest percentage of permanent involvement—80 per cent., according to Church. The early signs of this disturbance are looked for at the mitral valves in the largest proportion of cases, and yet the inflammatory change in the valve may not be the only factor in the production of the murmur. It is the belief of many clinicians that the toxic action of the blood on the muscular sphincter surrounding this opening is a factor of much potency in the production of the

incompetency. Then, too, when the toxemia is profound the myocardium suffers and we have not only the incompetency of the valves, but also the loss of contractility and conductivity of the muscle. The melancholy fact confronts us that in those cases characterized by an unusually high fever and profound toxic symptoms, the pernicious influence on the myocardium is so great as to be irreparable, and the individual goes through life with a permanently crippled heart. If, at any time, the kidneys give evidence of the slightest inflammatory change, the heart must be carefully watched and safeguarded until such time as the inflammatory changes in the kidneys have subsided.

To show you the importance of a careful scrutiny of the heart during these infectious processes, I quote from the report of an insurance company, made use of by Brown of Richmond, Va., in a paper read before the American Medical Association in 1908. This report covered 9,592 deaths in which the cause was given; these deaths occurred after the insured were past twenty-one years of age. I need hardly assure you these were all white men of standing in their respective communities, and had passed a more or less rigid examination before being accepted. Moreover, inquiry was made regarding the vocation, sanitary surroundings, habits of life, and whether the applicants were in any way connected with the sale or manufacture of alcoholic beverages, whether they were engaged in hazardous employment, and whether there remained the stigmata of any former illness; their ancestry was carefully considered to ascertain if perchance any family taint might exist; in addition to all this, it is safe to presume that the different organs of the body were subjected to the same careful scrutiny, and yet of these 9,592 deaths, 1,255 were caused by heart disease—surely an appalling number.

From an editorial in the *Journal of the American Medical Association* for January, 1908, I quote the following: "During the year just ended (1907) heart disease is reported to have caused many more deaths than in 1906; in Chicago and Boston, 13 per cent. more; in New York City, 29 per cent.; in Detroit, 26 per cent; in Philadelphia, 5 per cent." Thus it will be seen that deaths from heart disease are increasing rapidly and the most potent of all causes is the infectious fevers. In the years gone by the chief consideration of the clinician was the murmur produced by the constricted or regurgitant valve action, and while these parts of the heart's mechanism are not to be lost sight of in our study of heart disease, still the integrity and usefulness of the myocardium, the early determination of tricuspid leakage denoting danger, are now considered matters of more importance. Indeed, the crippled condition of the valves may go on for years, and yet the individual have good health. I have just spoken of tricuspid leakage denoting danger. While this is true in a general way, still, according to King, the tricuspid valves are normally barely competent, so that it takes but slight dilatation to render them incompetent and the reservoir function of the auricles and large veins is a wise provision of nature to take care of this. In accentuating the importance of valvular disease, the value attached to the study of the heart as a whole is too often lost sight of. Its ability to perform the work intended by nature, must be kept steadily in view; its rhythm, excitability, and conductivity are to be carefully investigated. The laity and, I regret to say, the profession also, too often speak of "heart failure" without in the least degree understanding what brings it about. Indeed, I think I am safe in saying that all the factors that produce it are not yet well understood. Mackenzie in his Oliver Sharpey lectures delivered before the Royal College of Physicians of London in 1911, says the essential cause is "changes in the heart muscle; other causes are contributing factors"; this is true, but by far the most important is what I have indicated. He says that about "70 per cent. of the cases of severe heart failure met with in general practice, with dyspnea and dropsy, owe their onset to auricular fibrillation." This is a condition in which either the single muscle fibers or the small bundles contract rapidly and apparently independently of each other, and as a result the auricles do not contract as a whole, but stand still, as it were, while all the fibers that make up the chambers are in constant motion. When the ventricles take on this condition, death ensues immediately, but not so with the auricles because of the fact that the fibrillation cannot pass along the bundle of His which connects the auricle with the ventricle. Unfortunately the determination of fibrillation of the heart cannot be made out by the general practitioner to a certainty, because the instruments necessary are expensive and delicate and are to be found only in very large hospitals, heavily endowed. Then, too, it requires long years of training to operate them and to interpret their finding correctly. However, when we have such symptoms as dyspnea, dropsy, enlargement of the liver, and abnormal fulness of the large veins with tricuspid leakage, we may suspect what is responsible for the patient's condition.

This paper would be incomplete without some reference in a general way to the treatment of the conditions here outlined that we may add "length of days" and comfort, as well as usefulness to the life of the cardiopath.

First of all, *prophylaxis*. Every effort should be made to prevent the young and, indeed, those in early middle life, from contracting the acute infectious diseases; those past middle life possess a certain degree of immunity. We shall also aid them as far as possible, when an infectious disease has been contracted, in warding off or avoiding the complications that so frequently arise. I would urge upon the general practitioner the great necessity of a more careful supervision and treatment of all infectious diseases, not only during the acute stage, but as well during convalescence, to the end that the heart may receive that protection its importance and liability to injury demand. If a heart lesion is found, I think it but fair to the individual that he be told of its existence, and its exact nature explained to him, that he may carry out the instructions of his medical advisor in an intelligent and careful way. The heart has wonderful recuperating powers, perhaps as much so or more than any organ in the body, and not infrequently the most pronounced cardiopath can lead a life of comfort and more or less physical and mental activity, if properly instructed and guided. However, he must be made to appreciate the consequences of disobediance. Rest, both physical and mental, is absolutely imperative. The patient should remain in bed and in the recumbent position until such time as the pulsations, both in number and rhythm, have reached the normal, whether that be one month or six. The diet, when and what to eat, exercise or work, and baths are fundamentally important and

must be carefully supervised. If these are all carefully looked after, many of these cardiopaths will need no medicine whatever. During the height of the preliminary attack of the acute infection, or during convalescence, the conditions are entirely different; particularly is this true of diphtheria and pneumonia. In the former, a very slow or a very rapid pulse is an ominous sign, and nearly always ends in death, unless very vigorous and well directed medication is instituted, and even then the outlook is markedly grave. For the former, digitalis in ten drop doses every three or four hours should be given, together with camphor hypodermically in doses of 10 or 15 minims of a 10 per cent. solution in olive oil. I have had most gratifying results from the use of small doses of morphine hypodermically. It steadies the heart and gives to the patient a mental and physical tranquillity that nothing else will. Indeed, I am not sure but it strengthens the systole even better than digitalis. If there is fever, the ice bag over the pericardial space is often productive of good. If there is no fever and the pulse is slow, hot applications should be substituted. Other remedies of like character will suggest themselves, such as strychnine, strophanthus, ether, caffeine, etc. There seems to be a diversity of opinion as to the value of adrenalin in these cases. Some speak very enthusiastically of it, while others think it of very doubtful utility. Personally, I have not had sufficient experience with it to speak either for or against.

In the early part of the paper, I have spoken of vasomotor paralysis, particularly in diphtheria, the result of the action of the toxins on the vasomotor center in the medulla. Some years ago, Dr. Bovaird of New York City gave to the Medical Society of the County of New York the result of very valuable study in these conditions, which I regret I have not at hand as I write. However, in cases of this kind he found the abdominal veins were abnormally full of blood, thus depriving the heart of the requisite amount of blood on which to contract, causing it to falter and finally stop. To counteract this, it was necessary to stimulate the coats of the blood-vessels to contract, by abdominal massage, the injection of saline solution, hypodermic injection of camphor, caffeine, and such other remedies as would restore to the blood-vessels their normal tonus.

Had I the time, and you the forbearance, much more could be said concerning the treatment of the changes that take place in the muscular and interstitial tissues of the heart in a class of diseases the general practitioner is so frequently called to treat which makes them the object of more than special interest, but time will not allow.

MODERN RÖNTGEN TECHNIQUE IN THE TREATMENT OF MALIGNANT CONDITIONS.

By MYLES W. JOHNS, M.D.,

UTICA, N. Y.

In covering the field of therapy I shall not attempt to go too much into detail, but simply to give to those interested in this branch of work an idea of how the treatment of to-day differs materially from that which many of us have been accustomed to use; as well as to give to the general practitioner some knowledge of what he may expect from this field of work.

In therapy there are three things we must thoroughly understand: 1, Measurement of vacuum of our tube; 2, measurement of amount of ray the patient receives; 3, filtering out the undesirable rays.

1. Measurement of Vacuum of Our Tube.—Instruments for this work are called qualimeters.

The Benoist scale is a round or oblong instrument which contains different thicknesses of aluminum. It may be likened to steps each presenting to the exposed ray one thickness more to penetrate than the preceding one. For comparison a portion of the scale is made of silver which gives about the same resistance to various degrees of penetration so that it makes a good medium for comparing with the other points of the scale. This instrument placed on a plate when the exposure is made readily shows how many layers of aluminum that particular tube is able to penetrate. This number is spoken of as such a number Benoist.

An instrument which I like very well on account of its simplicity as well as accuracy is the Bauer qualimeter. This is a round instrument which is unipolar. It is inserted in the line which leads to the cathode. As the tube is merely a resistance, the instrument inserted in this line registers the amount of energy which is necessary to produce the ray. The higher the tube the more energy it takes to overcome it and this instrument quite accurately measures this amount. This scale goes from one point up. The higher tubes register from seven to twelve. Thus, the higher tube would be spoken of as seven to twelve Bauer.

2. Measurement of Amount of Ray the Patient Receives.—Instruments for this work are called quantitometers.

One of the first quantitometers used was the Sabouraud scale. This consists of a pastille of barium platinocyanide, which under exposure to the Röntgen ray gradually changes from a brilliant yellow to the deeper shades of ochre. Tint B, or erythema dose, is the amount desired. Hampton's scale and Holzknecht's are varieties of this type.

Kienbock's scale consists of strips of sensitized paper which on exposure to the ray is so charged that by developing for a fixed time in a standard developer a color is obtained which may be matched with a scale and the shade noted. This scale runs from 2X to 44X, 10X being the equivalent to tint B of Sabouraud scale.

3. Filtering Out the Undesirable Rays.—Filters are used to eliminate the waves of short length which are particularly irritating to the skin and practically have no therapeutic effect.

Various thicknesses of leather, from chamois skin to sole leather, are used for the lighter types of filters, while metal constitutes the best in treating the growths in deeper tissues. Aluminum has come into use almost exclusively and can be had in 1, 2, and 3-mm. thicknesses. The 2 and 3 mm. are those commonly used in treatment of deeper malignant conditions.

In treatment it is desirable to give the maximum dosage without producing damage to the skin, aiming not to go beyond the erythema dose. By filtering the rays we can give twice the dose which was previously considered the erythema dose.

Treatment of Superficial Conditions.—Some do not use filters in this condition, others use chamois or leather, or the 1 or 2-mm. aluminum filter. Here the dose is 1 (tint B-10X-5H), or if filter is used, a double dose can be given. If the larger doses are

given with filter, always wait three weeks, as the reaction is slower.

Tumors of Mucosa and Serosa.—We do not get as good an effect in cases of involvement of the mucosa and serosa as when the epithelial surface is involved. I think this is often due to our not recognizing cases early, as these tissues are very vascular and the growth must be eliminated early or metastasis takes place. This is especially so in the tongue, but when the growth is removed at the earliest time possible followed by Röntgen treatment, the results seem superior to those of surgical treatment alone.

Sarcoma of the Maxilla.—Generally speaking, the results have not been satisfactory.

Rodent Ulcer.—Results have been very good, but it is questionable whether the zinc ionization or carbon dioxide snow is not preferable in the great majority of cases.

Deep Treatment.—Here we must have: High tube, full dosage, filter 3-mm. aluminum.

Malignant Conditions of the Breast.—In early cases where the growth is free, advise always surgical removal, followed by thorough Röntgen treatment. Bythell of Manchester has treated these cases for years, and states that he has known only one growth to recur. This came very soon after the operation and readily disappeared under treatment. In my own practice I usually make a röntgenograph of the chest and if metastatic conditions are not in evidence I follow with a course of treatment over the area of the scar and axillary region. In cases where there is metastatic involvement the dose must be the largest possible, and is given in the clavicular region, breast, and axillary regions; two doses in each place with 3-mm. aluminum filter. Treatment may be repeated in three weeks. If, as is often the case, the patient is sent for treatment with recurrence following operation, these cases can be kept in check for three to five years; old ulcers often clear up, pain is relieved, growths diminish in size and often disappear. These points make the treatment of considerable value and the patient is often made comfortable for months and even years.

Sarcoma.—Results here are better than in carcinoma or epithelioma. Barclay and Bythell report three cases which have apparently been cured. I have had one case which cleared up under the ray. Bulow Hansen reports a child ten years of age with sarcoma of the shoulder having considerable atrophy of muscles and failing health. This case improved rapidly under *x*-ray treatment, frequent radiographs being taken, each showing steady improvement until he suffered an accident resulting in his untimely death. A complete pathological examination of the tumor was made, and this showed that a large percentage of the sarcomatous areas which were rarified had filled in with new bone. Although there was still present some sarcomatous tissue, the disease was much more than arrested, the patient recovering the use of his arm, and his general health was improved.

In conclusion, I wish to state that there is yet much to be learned. But in the adoption of massive doses in the treatment of malignant conditions the results have certainly been superior to the fractional dose method. The accurate measure is scientific and we know that with small and often repeated doses cases may be stimulated and even malignant conditions produced. While we may divide these doses in two to four treatments the results are not the same as in one massive dose.

TWILIGHT SLEEP IN THE HOME.

By KENNETH F. JUNOR, M.D.,

BROOKLYN, NEW YORK.

Among nations where a more simple life than our own obtains, labor is a matter of very little anxiety and suffering. We have introduced the use of instruments, which are used, much more frequently than generally supposed, to hasten labor and, supposedly, to shorten suffering. Instrumental labor was fought as strenuously as any other innovation, but in reality by it much more damage and more permanent injury are done than can occur from the use of the twilight sleep. There seems little doubt that, in our highly nerve-strung and corset-wearing women, among whom childbirth is no longer a really natural function, nature has to receive aid. The immediate suffering and long-continued dread of labor, and the care involved in the raising of children, are lowering the birth rate dangerously. The nervous strain, lasting through months, and followed by the immediate nervous shock accompanying a difficult labor all influence more or less markedly the physical and mental condition and future of both mothers and children, hence the future of the race itself. Anything that involves no specific injury to mother or child, and at the same time relieves the long overhanging dread and final nervous shock of labor, is a matter of supreme national moment. And just here is where twilight sleep is, in the writer's opinion, of vital importance.

First, is it dangerous? The evidence from many thousands of cases testifies to not more than 0.5 per cent. of deaths having occurred—less than among ordinary labor records.

The drugs used are well known as to their immediate and remote effects, and the quantities used are so small that it is impossible to see how any permanent injury can follow. Undoubtedly great improvements in their application, as in everything else that is new, will soon follow their more extensive use.

My own experience has already taught me what I consider will, if generally adopted, render twilight sleep much safer and more effective, namely, the addition of sulphate of spartein. The most serious objection so far offered against twilight sleep is the danger of flushing in the mother, an indication of more or less interference with circulation; and, as sequelæ, cyanosis and suffocation in the child. Spartein, which is one of the greatest diuretics and heart tonics known, and has the specific effect of equalizing circulation, naturally prevents these untoward conditions.

Believing this treatment, with the added employment of spartein, a valuable addition to obstetric practice, I resolved to test its application in the case of labor in an ordinary home, and under ordinary conditions, it not having been as yet administered outside of a hospital. It was entirely successful, even without a graduate nurse. I ought to say that I escaped any cyanosis either in the mother or the child, although the conditions were such that cyanosis in the child would have been a certainty under the conditions of ordinary labor. The tendency in modern medical practice is too much towards making technique so difficult that it can be carried out only in a hospital. Thus the ordinary family physician is discouraged from undertaking many advanced relief measures, which he is really fully capable of carrying out with entire success.

With proper care the twilight sleep treatment, to the doctor who understands his business, is simple and perfectly safe for the patient; it does not interfere with the natural course of labor; it does not make a difficult labor any less difficult. It does relieve the mother from suffering in difficult labor; there lies its value. The nervous shock accompanying such labors, from which often the patient does not recover for weeks, is avoided by this method.

I firmly believe that the introduction of such amelioration of the pains of childbirth, and the removal of the dread of it will go far to restore the birth rate, and, as well, modify prenatal influences, now injurious to our children. Mothers, however, should not be encouraged to entertain the idea that the twilight sleep or anything else is going to remove the troubles of childbearing, but only to ameliorate them. There is good evidence for believing that the addition of spartein sulphate to the armamentarium of the twilight sleep, here recommended, is a distinct advance. In all probability it reduces narcosis amnesia, and unconsciousness, permits analgesia to the abolition of any suffering, securing on the whole such a complete reduction of shock that the patient emerges without exhaustion or impaired vitality.

One of the writer's most recent cases shows well how this method secures unimpaired vitality after labor.

I arrived at the patient's side to find her in a faint from exhaustion caused by the preliminary pains. I put her at once to bed and administered a grain of spartein sulphate, $1\frac{1}{2}$ c.c. of scopolamine, and 1 c.c. of narcophen. The pulse and respiration remained normal during the entire labor. She dozed or slept between the pains. She did not change her position during labor. I was obliged to ask her to let me know when the pains were coming, that I might measure their strength and efficiency. They were both strong and very efficient, as is indicated by the fact that I was only three hours in the house, leaving a perfectly happy and unexhausted mother, and a normal baby of eight and three-quarter pounds. There had been no amnesia, light sleep between pains, consciousness of labor, except of the third stage (when a few whiffs of chloroform were given), but no suffering at all. Surely this is ideal. This patient's three previous labors had all lasted over ten hours, and left her completely exhausted. I firmly believe this treatment of labor to rank as one of the greatest advances in medicine, as well as one of the greatest boons to the race, largely because it promises for a better race.

Twilight sleep requires a more continuous presence of the attending physician; this is undoubtedly a favorable condition in labor, necessitating as it does more care and supervision. What the writer considers one of the valuable, though incidental consequences of this treatment will be the restoration of confidence in, as well as the more careful study of drugs, and their more scientific use.

The question of amnesia is not of so much importance as its advocates claim. I believe too much importance has been attached to this condition of the abolition of memory. To my mind it makes little difference, so long as there is no sense of suffering, whether the patient remembers the things that have happened or not. It seems to me that this is also one of the things that is of too fanciful a character, like its name, partaking too little of the scientific to be readily accepted by a professional man. Practically I have found the twilight sleep entirely satisfactory without amnesia. I am not sure whether this condition may not be obviated by the use as I have suggested of the sulphate of spartein. There is a possibility of a desire to carry the anesthesia and amnesia to an extreme. Twilight sleep should be emphasized as simply and solely an amelioration of the suffering accompanying childbirth; not its entire abolition.

458 East Twenty-Ninth Street.

NASAL TUBERCULOSIS.

By JOSEPH COLEMAN, M.D.,

NEW YORK.

THE following case seems to me to be of sufficient interest to be placed on record:

Mrs. B. Z., aged 50, presented herself for treatment at the University and Bellevue Medical College clinic, Sept. 28, 1914, complaining of pain on the right side of the nose, which had been of about one month's duration, gradually growing worse, and now excruciating. Complained also of crusting and bleeding, from the right nostril only.

Patient is of the better class of clinic cases. Emaciated and anemic. Her weight ten years ago was 160 pounds, at the present time it is only 95, though she has not been conscious of any rapid loss of weight, particularly during the past two or three years. Coughs considerably and brings up large amount of thick, cheesy secretion. No night sweats.

The nose is considerably swollen, about twice its normal size, the swelling being mainly in the region of the tip. There is a good deal of redness and the nose is very tender to the touch over the right lateral cartilages.

Examination revealed a shallow, ovoid ulcer, about 1 mm. in depth, 12 mm. in length and 9 mm. in width, situated on the outer wall of the right nostril, at a point corresponding to the upper lateral cartilage. The ulcer had edges which were not sharp and well defined, and which gradually merged into the adjacent tissue. On its floor were seen numerous miliary tubercles. There was no area of redness or infiltration around the ulcer. All the mucous membranes were pale.

Patient had no syphilitic history, but a Wassermann test was made, which was reported negative.

The affected area was cocainized and a section taken which was sent to the laboratory for examination. Report, Oct. 2, 1914: "Specimen sent for examination shows epithelioid tuberculosis. Diagnosis: Tuberculosis of mucous membrane. Dr. D. S."

The patient did not reappear at the clinic until Oct. 19, 1914, about two and a half weeks after the first visit. During this time the ulcer had increased in depth and slightly in all other dimensions. Pain was still excessive, but crusting and bleeding not so profuse, probably due to the frequent cleansing, and to liberal applications by patient of yellow oxide of mercury ointment. Patient also has epilepsy and says that due to injuries received during a recent attack, she was unable to report for further treatment.

The case was referred to the medical department for chest examination, and was reported to have an extensive involvement of left upper lobe and beginning involvement on right side.

Tuberculosis of the nose is quite rare and by far the greatest majority of cases present lesions on the septal surface or floor, very seldom on the outer wall. Even when there is an ulcerative process which spreads from the septum to the floor of the nose, it rarely extends to the turbinated surfaces.

The general appearance of the nose might lead one to suspect acute follicular infection, though a history of one month's duration would cause one to suspect disease of a more serious nature.

It is interesting to consider in these cases the probability of nasal infection by the fingers. Examination of material removed from under the

finger nails of a number of tuberculous subjects has shown the presence of the tubercle bacillus; and how potent a factor this may be in causing further local infections is well worth serious thought.

Local treatment for the present consists in thorough cauterization with nitric acid C. P., patient keeping nose clean with hydrogen dioxide and preventing scab formation with the ointment mentioned before. An *x*-ray treatment has also been started. In addition systemic treatment is also being given.

59 West Ninetieth Street.

Medicolegal Notes.

Liability of Charitable Hospitals for Physicians, Nurses and Administrative Staff.—In an action against a hospital it appeared that the hospital charged its needy patients nothing for board or treatment, and charged the well-to-do for board an amount insufficient to cover the per capita cost of maintenance. It was held to be a charitable institution. The plaintiff came to the hospital suffering from some disorder of the stomach, became an inmate of the hospital, paying board, and after some weeks of treatment the house physician discovered a lump, which proved to be a fibroid tumor. He consulted the visiting physician, who advised an operation. The plaintiff's testimony was that the character of the lump, so the physicians informed her, could not be determined without an ether examination. She consented to such an examination, but notified the house physician that there must be no operation. She was taken at night from the medical to the surgical ward and prepared for an operation by a nurse. On the following day ether was administered, and while she was unconscious a tumor was removed. Her testimony was that this was done without her consent or knowledge. She was contradicted both by the visiting physician and the house physician, as well as by many of the attendant nurses, but for the purposes of the appeal, a verdict having been directed in favor of the hospital and affirmed by the Appellate Division, her narrative, even if improbable, was taken as true. Gangrene having subsequently developed in her left arm, necessitating the amputation of some of her fingers, she sought to charge the hospital with liability for the wrong.

The settled rule is that such a hospital as the defendant is not liable for the negligence of its patients and nurses in the treatment of patients. This exemption has been placed upon two grounds. The first is that of implied waiver. It is said that one who accepts the benefit of a charity enters into a relation which exempts one's benefactor from liability for the negligence of his servants in administering the charity. The hospital remains exempt though the patient makes some payment to help defray the cost of board. Such a payment is regarded as a contribution to the income of the hospital, to be devoted, like its other funds, to the maintenance of the charity. The second ground of the exemption is the relation subsisting between a hospital and the physicians who serve it. It is said that this relation is not one of master and servant, but that the physician occupies the position, so to speak, of an independent contractor, following a separate calling, liable, of course, for his own wrongs to the patient whom he undertakes to serve, but involving the hospital in no liability, if due care has been taken in his selection. On one or the other, and often on both of these grounds, a hospital has been held immune from liability to patients for the malpractice of its physicians. The reasons that have led to the adoption of this rule are, of course, inapplicable where the wrong is committed by a servant of the hospital and the sufferer is not a patient. It is therefore also a settled rule that a hospital is liable to strangers —*i.e.* to persons other than patients—for the torts of its employees committed within the line of their employment.

In the case at hand the wrong complained of was not merely negligence. It was trespass. Every human being of adult years and sound mind has a right to determine what shall be done with his own body, and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages. This is true except in cases of emergency, where the patient is unconscious and where it is necessary to operate before consent can be obtained. The fact that the wrong complained of was trespass rather than negligence, distinguishes this case from most of the cases that have preceded it. In such circumstances the hospital's exemption from liability could hardly rest upon implied waiver. Relatively to this transaction the plaintiff was a stranger. She had never consented to become a patient for any purpose other than an examination under ether. She had never waived the right to recover damages for any wrong resulting from this operation, for she had forbidden the operation. In this situation the true ground for the defendant's exemption from liability is that the relation between a hospital and its physicians is not that of master and servant. The hospital does not undertake to act through them, but merely to act upon their own responsibility.

The hospital undertook to procure for the plaintiff the services of a physician. It did procure them. It procured the services of the visiting physician and the house physician. One or both of those physicians (if the plaintiff's narrative was to be believed) ordered that an operation be performed on her in disregard of her instructions. The administrative staff of the hospital, believing in good faith that the order was a proper one, and without notice to the contrary, gave to the operating surgeons the facilities of the surgical ward. The operation was then performed. The wrong was not that of the hospital: it was that of physicians, who were not the defendant's servants, but were pursuing an independent calling, a profession sanctioned by a solemn oath and safeguarded by stringent penalties. If in serving their patient they violated her commands, the responsibility was not the defendant's; it was theirs. There was no distinction in that respect between the visiting and resident physicians.

It was claimed that notice to the hospital might be gathered from the plaintiff's statement to one or more of the nurses and to the assistant administering the gas that she did not wish an operation to be performed. It was held that nurses, like physicians, in treating a patient, are not acting as the servants of the hospital. The superintendent is a servant of the hospital; the assistant superintendent, the orderlies, and the other members of the administrative staff are servants of the hospital. But nurses are employed to carry out the orders of the physicians, to whose authority they are subject. The hospital undertakes to procure for the patient the services of a nurse. It does not undertake, through the agency of nurses, to render these services itself. If there are duties performed by nurses foreign to their duties in carrying out the physician's orders it was not in the discharge of such duties that the defendant's nurses were then serving. The acts of preparation immediately preceding the operation are necessary to its successful performance and are really part of the operation itself.

They are not different in that respect from the administration of the ether. Whatever the nurse does in those preliminary stages is done not as the servant of the hospital but in the course of the treatment of the patient, as the delegate of the surgeon to whose orders she is subject. The hospital is not chargeable with her knowledge that the operation is improper any more than with the surgeon's. The physician who administered gas and ether took no part in the operation, and it did not appear that he knew that anything would be done except make an ether examination. The plaintiff's statement to him, therefore, did not charge the hospital with notice. In any event he was not the servant of the hospital. His position in that respect did not differ from that of the operating surgeon. If he was a party to the trespass he did not subject the defendant to liability. Judgment for the defendant was affirmed.—Schloendorff vs. Society of New York Hospital, 211 N. Y., 125, 105 N. E. 92.

Furnishing Medical Services as Necessaries to Wife.—The Massachusetts Supreme Court holds that a husband is not liable for necessaries, in this instance medical and hospital services, furnished by third persons to his wife, living apart from him, on the theory of provision not having been made for her; she having, under Massachusetts Revised Laws, chapter 153, section 33, obtained an enforceable order of the Probate Court, still in force and complied with by him, for his making to her certain payments at stated times for her support.—Malden Hospital v. Murdock, Massachusetts Supreme Court, 105 N. E. 457.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

NEW GROWTHS INVOLVING THE TERMINAL BILE AND PANCREATIC DUCTS.

THIS subject is one that illustrates an important application of the new method of duodenal content analysis, a method that has already demonstrated its usefulness in routine clinical work. The duodenal tube enables one to determine whether or not the pancreatic juice and bile enter the duodenum, and in the former instance the degree to which either or both of these secretions enter the duodenum.

That duodenal content analyses furnish a means of making an early diagnosis of new growths involving the terminal bile and pancreatic ducts is the title of a thesis contributed by Burrill B. Crohn to the *American Journal of the Medical Sciences*, December, 1914. The contention is made, and apparently well substantiated by laboratory and autopsy studies, that complete obstruction of the bile or pancreatic ducts or of both is the result of tumors involving them and that other pathological conditions do not entirely obstruct these passages.

The complexity of this subject is revealed by the fact that new growths in this region may originate in any one of the following parts: the common bile duct, the ampulla of Vater, the duct of Wirsung, the papilla of Vater, the duodenal mucosa, and the head of the pancreas. The study of a number of cases including most of the above types, with the aid of duodenal content analysis, enables the author to draw the following deductions: Carcinomata of the common bile duct cause early and complete obstruction of the bile system, and may in their later extension, and frequently do, involve in addition the Wirsungian duct and completely obstruct it. Carcinomata of the ampulla of Vater and of the duct of Wirsung near the ampulla of Vater cause complete obstruction to both of the main duct systems. Carcinoma of the duodenal surface of the papilla of Vater is the more common type of tumor and progresses through two stages, an earlier one of obstruction to the ducts and a later one of necrosis and ulceration with secondary release of the dammed-up contents. Neoplasms of the duodenal mucosa usually grow rapidly and enmesh the mouth of the ducts to obstruct them. Carcinomata of the head of the pancreas frequently avoid the ducts early but later infiltrate them. The important fact that stands out among these deductions is that new growths in this region usually obstruct one or both ducts completely at some stage of their existence and that such obstruction is demonstrable with the duodenal tube.

Crohn cites an experience comprising 102 cases in which the duodenal contents were examined, including 50 cases of obstructive jaundice of doubtful origin, and states that he has met with no instance of complete closure of both the bile and pancreatic ducts which was not due to neoplastic formation. Stones that apparently completely block the common bile duct do not, as is shown by analysis of the duodenal contents, provide an absolute barrier to the entrance of bile into the duodenum. If stone is associated with tumor of the common duct the symptoms are those of tumor. Pancreatitis with rare exception blocks neither duct, and hypertrophic cirrhosis of the liver leaves both ducts free.

The importance of the use of the duodenal tube as a means of making an early diagnosis of new growths involving the terminal bile and pancreatic ducts is heightened by the fact that in their early stage these tumors are localized, relatively benign, and amenable to surgical treatment. Delay is attended by cholemia, hemorrhage, rapid emaciation, and the involvement of neighboring organs, with no prospect of relief by surgical intervention.

A PLEA FOR AUTOPSIES.

IN America very satisfactory progress has been made in surgery and bacteriology, but the advance in knowledge of chronic diseases and disturbed metabolism lags behind that of Europe. The report of a committee on inquiry into certain departments of this city attributes our backwardness in these branches of medicine to unfortunate legislation governing autopsies. Before the eighteenth century physicians knew nothing of the effects of disease upon the organs of the body, but in the middle of the eighteenth century Morgagni of Italy and in the latter part of the same century Bichat of France both conceived the idea that the organs of the body were affected by disease and that study of the conditions of these organs would determine the cause of death. Other physicians following in their footsteps discovered by autopsies what effects certain diseases produced in the bodily organs and thus were able to formulate a method of determining these effects before death.

In Europe hospitals are authorized to perform autopsies on almost all bodies. The University College Hospital in London in 1912 performed them in 84 per cent. of the deaths. In most German hospitals over 90 per cent. of the deaths are followed by autopsy, and the Allgemeines Krankenhaus in Vienna has the unique distinction of 99 autopsies for every 100 deaths. In contrast to these European ideals the hospitals of the United States make a poor showing. Thus, Bellevue performs autopsies in about 10 per cent. of the deaths, Boston City Hospital 9 per cent., and Philadelphia General Hospital 10 per cent. A few of our hospitals have a higher rate. Most notable of these is Johns Hopkins, where the percentage reaches 62.8. Bellevue Hospital may be taken as a typical example of the results of

autopsy legislation in the United States. Although it possesses the finest pathological laboratory building and equipment in the country and unlimited material it is unable to utilize its opportunity on account of the ruling of the Commissioner of Charities (in 1910) that unclaimed dead bodies belong to the medical colleges and must be delivered to them without autopsy unless authorized by written consent of the college or performed by the direction of the coroner or the district attorney. The result of this rule is that much good autopsy material is wasted, because it has been shown by the committee conducting this investigation that the medical colleges of New York City received during the year 1912 a total of 661 bodies, when the most liberal calculations of their actual needs did not put the required number in excess of 342.

The immense value of the knowledge gained by a comparison of clinical diagnosis with postmortem findings is clearly shown by the report made on behalf of the committee by Dr. Horst Oertel, formerly Chief Pathologist of the Russell Sage Pathological Institute located at the New York City Hospital. He found that in 388 autopsies only 52.3 per cent. of the clinical diagnoses were confirmed. At that rate, of the 3,170 deaths occurring at Bellevue in the year 1912, there would have been 1,512 from causes not fully determined. In view of the foregoing facts it is not difficult for us to agree with the committee that our laws should be amended to permit hospitals to perform autopsies except when expressly forbidden by the nearest relative within forty-eight hours after death, and that they should be performed upon the bodies of all persons dying in public institutions and remaining unclaimed for forty-eight hours after death, unless deceased had signed a written request to the contrary, it being of course understood that such a proportion be reserved as may be legitimately needed for the use of medical colleges.

INFECTION OF THE PLEURA.

Dry pleurisy, pleurisy with effusion, and empyema are obviously rather closely related pathologically, and the differentiation is made between them solely on the basis of the character of the exudate. In an endeavor to determine the underlying factor in the resistance of the pleura to infection, and further as to what controls the degree of pleural response to irritation, Floyd has obtained some very interesting results (*Jour. Med. Research*, 1914, XXXI, 261). The high resistance of the pleura to infection has always been known in a general sort of way, but has not been sufficiently appreciated. A certain degree of pleural involvement is always present in lobar pneumonia and by far the most frequent cause of empyema is the pneumococcus, yet empyema develops in a comparatively small percentage of patients with pneumonia. Working with guinea-pigs and rabbits, Floyd found that the injection into the pleural cavities of emulsions of dead streptococcus pyogenes, pneumococcus or staphylococcus aureus which had not been washed usually produced an acute fibrinous pleurisy, while if the organisms had been washed free from bacterial products the injections were without effect. When the injections were made of living organisms practically no effect was produced until the dose was large enough to result in a fatal sepsis when the pleural cavity was usually found to contain fibrin and a little fluid, but in no case any condition resembling empyema. In another series of experiments the animals were first subjected to infection in other parts of the body or were treated with extracts or autolysates of the organism concerned. In this series there were several animals which showed the presence of a more or less purulent fluid in the pleural cavity. This work is somewhat along the line of that on aggressins or that more recently published by Zinsser and Dwyer on proteotoxin or anaphylatoxin (*Jour. Exper. Med.*, 1914, XX, 582). Certainly it shows that the pleura is exceedingly well able to take care of itself so far as bacteria alone are concerned and that it yields only when the bacterial forces are aided by the presence of some irritant or toxic material the nature of whose action is still unexplained. An attractive explanation is that given by Froin as quoted in Floyd's paper. When the bactericidal action is rapid after inoculation there is little chemiotactic action, the destruction of the organisms takes place rapidly, and any exudate is merely serous. If, however, the animal's defensive powers are weakened by the presence of infection elsewhere, or if the defensive powers of the bacteria are enhanced by the action of aggressins or proteotoxins, then the bactericidal action is slight, chemiotactic action is profound and exudate in the pleural cavity will be purulent. Unfortunately this does not correspond entirely with clinical findings since it is not always those who are the most ill with pneumonia who develop empyema. It is the best theory that has been offered up to the present time, however, and in immunity it is not often that an hypothesis can be found which will coincide completely with all the accepted clinical observations on the subject.

Mobilization Typhoid.

This phase of typhoid fever is one that requires special consideration, because it has been prevented by antityphoid inoculation, notably in the Texas mobilization of the United States troops several years ago. It seems from the experience of the present war that these mobilization epidemics may be quickly jugulated even after they have had a fair start. At a meeting of the Aerztlicher Kreisverein at Mainz on October 23 (*Münchener medizinische Wochenschrift*, December 1) Curschmann discussed this subject at length. Typhoid appeared soon after the assembling of large bodies of troops and could hardly have been either waterborne or foodborne. The victims were at once isolated and search was made for carriers with generally negative results so far as the troops were concerned. Suspicion rested strongly on the family of an innkeeper, in which typhoid had occurred repeatedly within the past twenty-five years. The suspicion could not be proved against this family, but it was submitted to rigorous measures for the public weal. Some technically typhoidal soldiers (serodiagnosticated) were apparently in good health; while there were also ordinary cases of walking typhoid. Senile

typhoid was also recognized, characterized by persistent subfebrile temperatures and tachycardia; as were also certain types of the disease which were masked by unusual localizations. A general round up along these lines with prompt isolation seemed sufficient to abort the threatened epidemics of mobilization typhoid.

Yaws and Syphilis.

THERE has long been a difference of opinion among authorities as to the unity or otherwise of syphilis and yaws and this question is still a moot one. Dr. C. S. Butler, Surgeon U. S. Navy, discussed the matter at some length in a paper read at the March, 1914, meeting of the Manila Medical Society (*United States Naval Medical Bulletin*, October, 1914). The author expresses himself a believer in the theory of duality of viruses as between yaws and syphilis, but confesses that many facts are better explained on the basis that yaws and syphilis are but different clinical manifestations of the same disease. He lays stress on the point that there is no fixed base line from which the two fields of yaws and syphilis can be surveyed. Those tests and reactions in immunity which are held as nearly absolute often are not to be relied on in the face of actual facts. One of the features of yaws which seem to distinguish it from syphilis is that yaws is a tropical disease while syphilis is pandemic, but the strict limitation of yaws to the tropics appears to Butler to be one of the strongest indications that in it we are simply dealing with syphilis. The paper by Butler, though interesting and suggestive, leaves the question where it was. However, it is a valuable contribution to the subject because it places the present situation as regards theory and facts brought out by the study of yaws and syphilis in a clear and concise manner.

News of the Week.

Sanitation on the Isthmus.—The report of Dr. Charles F. Mason, chief health officer of the Canal Zone, states that during October the total number of deaths from all causes among the 38,416 employees was 23, of which 15 were from disease, giving a rate of 4.68 per thousand, as compared with 5.31 for the preceding month and 5.14 for the corresponding month in 1913. Among the 36,395 residents of the Canal Zone there was a total of 49 deaths; of these, 42 deaths were from disease, giving a rate of 13.85 per thousand, as compared with 13.11 for the preceding month and 15.91 for the corresponding month of last year. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

Health of New York City.—The death rate of this city for the week ending January 16 was 14.49 per thousand, a decrease of .37 of a point compared to the corresponding week last year, equivalent to a relative decrease of forty-one deaths. The death rate for the first three weeks of this year was 14.73 per thousand of population, as against 14.62 during the same period last year. During the past two weeks there has been a large increase in the deaths from bronchitis and bronchial and lobar pneumonia.

No New Hospital Ship for the Navy.—It is reported that the Secretary of the Navy had intended to purchase a modern steamship to be converted into a hospital ship, but that the plan was blocked by Secretary Bryan who feared that the addition of another hospital ship to the Navy would be unneutral or at least might make the impression that the United States was looking for trouble somewhere. The Secretary of State probably thinks that a hospital ship, like his army of one million men, could be created over night if occasion for it arose.

For the Improvement of Sanitary Work in New York State.—The State Public Health Council recently urged upon Governor Whitman the need for more efficient, better trained, and better paid health officers, who could afford to devote more time to the work and who should be required to do so.

Dr. E. F. Bashford has resigned the post of general superintendent of the Imperial Cancer Research Fund, which he has held for the past eight years.

Dr. Margaret Sullivan has been appointed a member of the Jersey City Board of Education.

Dr. John M. Peters, Superintendent of the Rhode Island Hospital, Providence, was the recipient on January 5 of a handsome silver coffee service, the gift of the graduate nurses of the institution upon the completion of twenty-five years of service as head of the hospital by Dr. Peters.

Dr. William Hallock Park has resigned as Dean of the University and Bellevue Hospital Medical College in order to devote all his time to the duties of Director of Laboratories of the Department of Health.

Alumni Association of the Knickerbocker Hospital.—The annual dinner of this association will be held at the Hotel McAlpin on Thursday evening, February 11, at 7:30. The Secretary-Treasurer of the Association is Dr. J. E. Lumbard, 1925 Seventh avenue, New York City.

Freak Legislation in Massachusetts.—The *Boston Medical and Surgical Journal* says that among many important pieces of medical legislation to be brought before the Massachusetts legislature during the present session is one whose obvious absurdity should lead to its immediate defeat. It is a bill to regulate the condition of surgical practice which provides that "No surgeon, physician, dentist, nor other person, performing, directing, or assisting at a surgical or dental operation upon a human, either on public or private property in this State, shall wear the hirsute appendages commonly known as moustache and beard." Weird bills of this sort were at one time not uncommon in some of the younger States, but that the staid old Bay State should be giving herself up to such foolishness is distressing.

Belgian Physicians' Relief Fund.—In his stirring appeal for aid for the Belgian physicians, Prof. Charles Jacobs of Brussels states that 1,000 doctors are poverty-stricken, and that 2,000 to 3,500 doctors are suffering cruelly through this war. That 2,000 physicians need to be supplied the necessities of life would seem a low estimate. It is probable that the physicians' families will average four members. That means that 8,000 members of physicians' families are dependent upon outside contributions. Four dollars and forty cents will supply sufficient food to sustain life for four for one month. Belgian physicians and their families, therefore, absolutely need at least $8,800 worth of food every month. For the first month, contributions of American physicians aggregated $1,414. Will the medical profession of America accept its opportunity and meet its share of this responsibility by prompt and repeated contributions? Every cent of every dollar contributed will be available for the purchase of

supplies as the carrying charges are provided for by the American Commission for Relief in Belgium. The first $1,000 contributed have been expended by the Executive Committee for food and supplies, and the packages properly labeled have been started for their destination. The following is a full list of names of all contributors up to January 16:

Union Trust Company, Pittsburgh, Pa....Banking Facilities.
Sterrett & Acheson, Attys., Pittsburgh, Pa....
Professional Service.

Dr. Frank Overton, Patchogue, N. Y.	$25.00
Dr. Franklin H. Martin, Chicago, Ill.	100.00
Dr. F. F. Simpson, Pittsburgh, Pa.	100.00
Dr. S. Peskind, Cleveland, Ohio.	25.00
Dr. & Mrs. George C. Smith, Mansfield, Ohio.	5.00
Dr. Samuel Ayers, Pittsburgh, Pa.	20.00
Dr. Edwin Walker, Evansville, Ind.	25.00
Dr. Boleslaw Lapowski, New York.	10.00
Dr. Thos. E. Satterthwaite, New York.	20.00
Dr. Thomas L. Stedman, New York.	25.00
Dr. Richard E. Eustis, Boston, Mass.	10.00
Dr. Mark W. Richardson, Boston, Mass.	10.00
Dr. Wm. Allen Pusey, Chicago, Ill.	25.00
Dr. M. C. Shelton, Joplin, Mo.	5.00
Dr. Henry F. Walker, New York.	25.00
Dr. Boyd Cornick, San Angelo, Tex.	2.50
Dr. David W. Cheever, Boston, Mass.	25.00
Dr. Virgil P. Gibney, New York.	25.00
Dr. John B. Murphy, Chicago, Ill.	100.00
Esther F. Boland, Boston, Mass.	5.00
Dr. Chauncey W. Norton, Saranac Lake, N. Y.	25.00
In Memory of H. H. C., Boston, Mass.	10.00
Dr. S. J. Meltzer, New York.	15.00
Dr. David Bovaird, New York.	25.00
Evelyn G. Manter, Winthrop, Me.	10.00

Dr. Wm. Van V. Hayes, New York.	25.00
Drs. Parker & Parker, Peoria, Ill.	5.00
Dr. Heman B. Chase, Hyannis, Mass.	10.00
Dr. John B. Wheeler, Burlington, Vt.	25.00
Dr. Stuart McGuire, Richmond, Va.	50.00
Dr. John G. Clark, Philadelphia, Pa.	50.00
Dr. F. R. Underwood, Seattle, Wash.	5.00
Dr. Abraham Jacobi, New York.	100.00
W. A. M., Ossining, N. Y.	2.00
Dr. Theodore C. Janeway, Baltimore, Md.	15.00
Dr. Isaac M. Heller, New York.	5.00
Dr. S. H. Miller, Joplin, Mo.	5.00
Dr. B. F. Saylor, Redding, Cal.	10.00
Dr. J. Wolf, Pittsburgh, Pa.	10.00
Jasper Co. Medical Society, Joplin, Mo.	10.00
Dr. Sidney A. Chalfant, Pittsburgh, Pa.	10.20
Dr. Frederick Abbe, Boston, Mass.	10.00
Dr. J. Riddle Goffe, New York.	25.00
Dr. Henry F. Graham, Brooklyn, N. Y.	5.00
Total	$1,414.00

Belgian Relief Organization.—The Belgian Relief Commission announces the completion of a system for the collection of relief supplies in the United States and their distribution in Belgium. This organization includes a line of thirty-one steamships, which will in the future ply on regular schedule between ports of the United States and Rotterdam. Arrangements have been made with the Post Office Department and the express companies for the shipment of small parcels by individuals. It is now possible for any person in any part of the country to ship to the nearest assembling depot, at the expense of the commission, packages which will be held until carloads have accumulated, after which they will be sent to the seaboard for ships of the relief line.

Colleges Give Red Cross Ambulances.—Students of Yale have given twelve and Harvard students five automobile ambulances to the Red Cross for use in the war zone. Each of the ambulances is equipped to carry two wounded men.

The American Women's War Relief Fund.—American women resident in England recently held a meeting to review the work done by their organization since the beginning of the war. Up to the present a total of $219,550 has been subscribed toward the Hospital, and the urgent need of more funds was emphasized. The chief surgeon of the Hospital, Dr. Howard W. Beal, said that a pathologist was needed and the American Red Cross had promised to supply one and also to send as many surgeons as might be required.

Opposition to the Tax on Dentifrices.—A committee of New York physicians and dentists has been organized to petition Congress to revoke the war tax on tooth washes, pastes, and powders on the score that it is a severe blow to the work that has been done by State and municipal governments in behalf of mouth hygiene.

Guinea-pigs for Food.—The Medical Society of Frankfort-on-the-Main has issued an appeal to the German public to undertake the extensive breeding of guinea-pigs for food purposes. It is stated that the meat of this little animal is delicate and tasty, and as the creatures are so prolific it is believed that a large amount of food can be thus provided at small cost.

Medical Society Elections.—The Walker County (Ala.) Medical Society met at Jasper on December 12 and elected the following officers: *President,* Dr. J. M. Miller of Cordova; *Vice-President,* Dr. T. Manasco of Carbon Hill; *Member of the Board of Censors,* Dr. J. M. Miller of Cordova.

The Four Counties Medical Association, comprising the counties of De Witt, Lavaca, Victoria, and Calhoun, Tex., met at Cuero on December 16 and elected the following officers: *President,* Dr. M. Duckworth, Cuero; *Vice-President,* Dr. J. E. Pridgen, Thomaston; *Secretary and Treasurer,* Dr. B. T. Norwiercki, Yorktown; *Delegate to the State Medical Association,* Dr. G. W. Allen, Yorktown; *Alternate,* Dr. J. M. Lackey, Cuero.

The Simpson County (Miss.) Medical Association met at Mendenhall on December 12 and elected the following officers: *President,* Dr. Tillis Gandy of Weathersby; *Vice-President,* Dr. W. F. Stroud of Pinola; *Secretary-Treasurer,* Dr. J. L. White of Pinola; *Censors,* Drs. J. H. Kennedy of Pinola and A. E. Kennedy of Magee; *Delegate to the State Association,* Dr. J. L. White of Pinola.

The Mobile County (Ala.) Medical Society, at a meeting held December 12, elected the following officers: *President,* Dr. J. Tunstall Inge; *Vice-President,* Dr. Daniel T. McCall; *Secretary,* Dr. W. W. Scales; *Treasurer,* Dr. Angelo Festorazzi; *Librarian,* Dr. John Rush; *Censors,* Drs. Harry T. Inge and Gilman Winthrop.

The Carroll County (Ga.) Medical Association elected the following officers at a meeting held at La Grange on December 21: *President,* Dr. R. J. Goodwyn of Poopville; *Vice-President,* Dr. W. L. Fitts of Carrollton; *Secretary and Treasurer,* Dr. R. E. Foster of Carrollton.

The Richmond County (Ga.) Medical Association elected the following officers at a meeting held in Augusta on December 11: *President,* Dr. R. V. Lamar; *Vice-President,* Dr. Ashby Hull; *Secretary and Treasurer,* Dr. J. C. Wright; *Member of the Board of Censors,* Dr. C. I. Bryans.

The McNairy County (Tenn.) Medical Society held its regular meeting at Selmer on December 18, electing the following officers: *President,* Dr. Charles Chambers of Michie; *Vice-President,* Dr. W. T. Bell of Selmer; *Secretary,* Dr. T. G. Jackson of Gravehill.

Deaths of Foreign Medical Men.—Dr. Klaus Hanssen, chief physician of the Municipal Hospital, Bergen, Norway, and a member of the Norwegian Academy of Medicine, died recently at the age of 71 years. Dr. Hanssen was a leader in the fight against tuberculosis in Norway.

Dr. Léon Lereboulet has died in Paris. He was born in Strasbourg, December 14, 1842. He served in the medical corps during the Franco-German war. He was one of the editors, with Dechambre and Duval, of the "Dictionnaire usuel des sciences médicales."

Dr. Suñé y Molist of Barcelona died recently. He was one of the editors of the *Gaceta Médica Catalana* and was a member of the Real Academia de Medicina.

Obituary Notes.—Dr. Joseph Piersol of Bellaire, O., a graduate of the Medical Department of the University of Pittsburgh in 1890, and a member of the Ohio State Medical Association and the Belmont County Medical Society, died suddenly on January 1, while visiting at the home of a patient.

Dr. Robert Liggett McGrew of Pittsburgh, Pa., died on December 18. He was graduated from the Bellevue Hospital Medical College in 1886.

Dr. Jacob Lyman Horr of Westbrook, Me., died December 22, at the age of 73 years. He was born in Waterford and was graduated from the Bowdoin Medical School in 1869. After practising for a few years in Oxford he removed to Westbrook.

Dr. Henry Dusenbury of Brooklyn, N. Y., died on December 30, at the age of 80 years. He was born in Albany and was graduated from the College of Physicians and Surgeons in this city in the class of 1866. He was at one time in the Medical Corps of the U. S. Army.

Dr. John W. Smith, a retired physician of Detroit, died at his home in that city on December 21 at the age of 84 years. He served through the Civil War in the medical corps of the U. S. Army, being retired with the rank of major.

Dr. Joseph Hunt Wilson of Somerville, N. J., a graduate of Princeton University in the class of 1846, and of the New York University Medical College in 1850, for some years a member of the staff of the New York Custom House, and at one time editor of *The Unionist Gazette* of Somerville, died at his home on January 2, aged 86 years.

Dr. Dudley Peter Allen of Cleveland, O., a graduate of the Harvard University Medical School, Boston, in 1880, emeritus professor of surgery in the Western Reserve University School of Medicine, and a member of the American Medical Association, the American Surgical Association, the Ohio State Medical Society, and the Cleveland Academy of Medicine, died in New York, after a short illness, from pneumonia, on January 6, aged 62 years.

Dr. David J. Loring of Valparaiso, Ind., a graduate of the Rush Medical College, Chicago, in 1878, a member of the Indiana State Medical Association and the Porter County Medical Society, and secretary of the latter, died at his home, from cancer of the stomach, on December 29, aged 66 years.

Dr. Charles Ross Jackson, formerly of New York, a graduate of the Medical Department of Yale University, New Haven, in 1888, and a member of the American Medical Association, the New York State and Essex County Medical Societies, and the West Side Chemical Society of New York, died at his home at Lake Placid, on January 4, aged 47 years.

WAR NOTES.

TETANUS—TINCTURE OF IODINE IN FIRST AID PACKETS—MINER'S NYSTAGMUS IN THE TRENCHES—BACTERIOLOGICAL RESEARCH AT THE FRONT—LONDON DOCTORS AT WORK.

London, January 4, 1915.

The war is changing many of our ideas regarding the value and kind of antiseptics, and their relative value in preventing infection in the field. As we know, the territory now occupied by the opposing armies in Marne and Flanders was under a high state of cultivation, and has been so frequently treated by enrichment of manure, that it is undoubtedly a fruitful soil for the breeding of dangerous microorganism. Like our own Long Island in early days, it is noted especially for the prevalence of tetanus in ordinary times. As on the south side and about Moriches, the wound of a fish bone would very likely be followed by "lockjaw," and farmers would take their male colts to Montauk to be castrated, so would the injured Belgian farmer at times flee to a region where he was immune. At present the first thing, if possible, is to give the wounded soldier a good dose of antitetanus serum, and when fighting goes on practically in the mud full of the special germ, this precaution is undoubtedly valuable and life saving.

The use of iodine seems to be most general just at this time, and the French government furnishes each soldier with a small packet containing an *ampoule* with a small brush. An English pharmacist has improved this by supplying an *ampoule* filled with a strong tincture, the friable stem of which ends in a pledget of gauze or cotton. When the wounded man simply breaks the terminal stem the bandage is soaked with the contents, and with this he thoroughly swabs the wound. It is said to be far more efficacious than the simple application of gauze, which is certain to favor the retention of any imprisoned bacteria. This is on the theory that in anaerobic wounds the dangerous bacteria of tetanus, gangrene, malignant edema, and other diseases thrive in situations when air is excluded; in fact, after the first application of iodine there is little or no dressing applied. In many cases the wound heals by first intention.

Many strange conditions are seen by the surgeons. Dr. Jex-Blake, who is now a surgeon at the Denmark Hill Hospital of Kings, told me that he had seen a case of miner's nystagmus in a man who had been lying in the trenches and had been doing sappers' and miners' work. He had originally been a Welsh miner and had had this affliction when at work, but it disappeared on changing his occupation, and he remained free for years until the labor at the front was resumed under the old conditions. This required him to be on his side and excavate the earth above him. The condition was so serious that he had to leave the army.

The activity of those engaged in bacteriological research is simply astonishing, and the other day when we heard that cholera had broken out among the Russian troops, an investigator was sent to procure a specimen of the particular cholera bacillus that he might prepare in time a serum that would contain the specific antibodies, should this special form of cholera break out among the forces in the Belgian and French territory.

This thoroughness is seen in all branches of hos-

pital and research work. The best men devote as little time as possible to office or other work, but actually see their ordinary patients in khaki, and may be seen going from one point of London to another at all hours, all intent upon carrying out the sensible orders of the head of the medical department, who, in the absence of Sir Arthur Slogget at the front, is Sir Alfred Keogh, who by the way has been in the United States, where he is very popular.

ALLAN McLANE HAMILTON.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE WAR, TREATMENT OF WOUNDS AT THE FRONT AND AT THE BASE—DIVERSE SURGICAL VIEWS—ANTISEPTICS AND ASEPTICS.

LONDON, December 31, 1914.

OUR talk is still of war and the press reflects our diverse opinions on its various aspects. In previous letters I have reported some of these, especially as expressed at Societies. Last month's discussion on the treatment of wounds in war at the Medical Society is recalled by Sir Anthony Bowlby who says that for some six weeks he has observed such wounds under different conditions from those who joined in that discussion. For the last three of these weeks he was at the clearing stations to which wounded are taken after dressing in the field ambulances—some within a few hours, others after eighteen to twenty-four—more rarely on the second day. But motor ambulances cannot take them at night, as their lights would draw fire. The latest cases at the field ambulances are fractures of lower extremities or of the spine, as they cannot help themselves as those can who are only hit in the arms or have slight flesh wounds. Many have been left lying in wet mud or manured fields a long time and their wounds have been contaminated with these, blood, or other septic matter. Sir A. Bowlby, who you may remember is consulting-surgeon to the expeditionary force, found the rifle wounds in this war different from those he observed in South Africa. The new bullet inflicts a more severe injury and at very close range, at which it is frequently inflicted, produces an "explosive effect." He has seen the greater part of the muscles of the forearm protruding through a rent in the skin and fascia in the case of a shot within three or four yards. But if the bones be struck at these distances the wounds may be so severe as to resemble shell wounds.

Shrapnel wounds are twofold—from its bullets or from fragments of the case. The former vary with the height from the ground when the explosion takes place as well as with its velocity at the time; so again with its distance from the man. Howitzer shells contain no bullets and the bursting charge usually explodes on striking the ground. Accordingly the wounds are caused by fragments, some of which may weigh several pounds while others are quite small. Howitzer wounds are the most horrible of all and so the most fatal. They are often contaminated with mud, clothing, or other things carried in by the part of the shell causing the wound.

Passing to the principles of treatment Sir Anthony points out that the exigencies of war only permit at clearing stations equipment which can be moved as necessitated. As there are no tents or huts any available building must serve as shelter or rather several, for one of adequate size cannot be expected, and there is no time perhaps to clean. Nor are there any beds, and patients have to lie on the stretchers on which they are brought. In towns some beds may be obtained. A clearing station will be equipped for 200 cases, and such a one has had to dress above 1,000 in one day. The pressure in such event must be left to imagination. The dressing must be *anti*septic—the idea that in the clearing stations it may be *a*septic is erroneous. It is impossible to have a general hospital at the front, and clearing stations must be very portable. In the recent war 1,200 wounded a day had to be treated in the clearing stations, and on one day over 3,000. The pressure was greater because they were not distributed over all the stations, so that on some occasions every yard of floor space was taken up by stretchers coming in by hundreds every two or three hours. But every case was fed, dressed, and cared for on the day of arrival, the great object of the clearing station being to treat the patients temporarily and send them on to the base hospital and be ready for fresh cases from next day's fight. After dressing it is necessary to transfer to ambulances and hospital trains.

The question of antisepsis, alluded to above, has been a good deal talked about in reference to the present war. One meets, now and again, a person who is imbued with the notion that asepsis can be carried out in military surgery, but those who have served in a clearance station are not among them, but will tell you that aseptic gauze and sterilized water are not to be trusted against wounds contaminated with soil reeking with organisms. Sir R. J. Godlee calls them broken reeds compared with a true antiseptic like carbolic acid, preferably pure, for the first dressing of a wound probably infected with tetanus or spreading gangrene besides other organisms. He calls to mind Lister's early compound fracture cases in which undiluted carbolic acid was freely used and no ill effect took place and adds that diluted with blood or serum it is less potent than with water as also is bichloride. The wound should therefore be as dry as possible for disinfection. In a suspicious case he favors a prophylactic dose of antitetanic serum.

Sir Victor Horsley seems to be shocked with such vigorous antiseptic measures and in a postscript to a letter to the *British Medical Journal* says: "As though the conditions surrounding wounds in the present campaign were not sufficiently complicated, there has now been shown to me a memorandum, purporting to be issued by the War Office and prepared by Sir Rickman J. Godlee, Bart., in which the terrible proposal is made to swab out recent wounds with pure liquid carbolic acid!"

Drs. Purves Stewart and J. T. C. Laing record in last week's *Journal* a case of tetanus in which the disease steadily advanced in spite of antitetanic serum treatment but yielded to hypodermic injections of carbolic acid. They used a 5 per cent. solution of which they injected into the abdominal wall 2 c.c. every two hours. On the second day the spasms being greatly reduced the injections were given every four hours; on the third day a slight increase of spasms was met by the two-hourly dose for a couple of days, after which convalescence was uninterrupted. The thoracic and abdominal muscles were the slowest to lose their tonic spasms. This is Baccelli's treatment under which he recorded a gross mortality of 17.4 per cent. in 190 collected cases. It is suggested that cases in the present war should have the chance of this treatment which would not supersede preventive antitoxin, being only resorted to when the disease had developed.

5. Visceral Ptosis. A Review. J. T. Williams.
6. A Few Notes on the Treatment of Anteposed Uteri. H. T. Hutchins.

1. The Tonsils and Tuberculous Cervical Adenitis.—G. L. Richards states that it has been repeatedly demonstrated that tubercle bacilli can be made to invade and pass through the faucial tonsil without producing tuberculosis of the tonsil itself. Tuberculous adenitis is not necessarily accompanied by a tuberculous tonsil. The tonsil, however, may be the portal of entry for the infection. The author recommends that in all cases of cervical adenitis the tonsil be removed as the first procedure.

2. Treatment of Tuberculous Cervical Adenitis.—H. D. Chadwick details the routine treatment of tuberculous cervical adenitis in children, as carried out at the Westfield State Sanatorium, Massachusetts, as follows: If the patients have no more than one degree of temperature, and have no other signs of active pulmonary disease, they are given tuberculin treatment, the bacillen-emulsion being used. The initial dose is one-millionth of a milligram and the course of treatment extends over a period of about six months until the maximum of ten milligrams is reached. As the result of this treatment the glands decrease perceptibly in size and the area of dullness over the hilus becomes less pronounced. Surgical interference is necessary to remove only such glands as have become caseous or fibroid. Extensive dissections are unnecessary in these cases as the small recently diseased glands that are left disappear under the influence of tuberculin treatment.

5. Visceral Ptosis.—J. T. Williams finds from a review of this subject that none of the various methods of treatment has proved universally satisfactory. But few men have carried out any of the outlined procedures with the vigor ordinarily applied to the treatment of other pathological conditions. Concerning the surgical treatment, the amount of work so far done is too small upon which to base an opinion. The number of surgical procedures which a single case demands must prohibit operative treatment in a considerable proportion of cases. Gymnastic treatment must be of great benefit early in the process, but unfortunately the anatomical changes are so extensive in advanced cases that but little help can be expected from exercises. Corsets, although only palliative, and never quite relieving the patient's symptoms, nevertheless are of much value, and probably in advanced visceral ptosis will continue to give more comfort than anything else. The greatest prospect for improvement lies in prophylaxis, as pointed out by Goldthwait. Certain individuals are predisposed to ptosis by anatomical peculiarities. These patients should be easily recognized by their tendency to the ptotic figures, and by general muscular insufficiency. Such persons taken early in life, their attitude corrected, and their muscles developed by exercise and proper food, it should be possible to prevent the development of extreme cases of visceral ptosis.

6. Treatment of Anteposed Uteri.—H. T. Hutchins concludes that the position of the fundus is of little importance from a symptomatic standpoint. Descent of the cervix, irrespective of the position of the fundus, causes a drag on the parietal peritoneum of the pelvis with congestion of the ovarian veins. One must recognize this descent as a symptomatic factor and not hesitate to suspend an anteposed uterus when such descent is present. In every case, before operating, one should prove by temporary means to the patient's and to one's own satisfaction that the malposition is the cause of the patient's symptoms. One should then suspend only those few selected cases in which a suspension is necessary.

1. Metastatic Complications of Otitis Media.—By S. Oppenheimer. (See MEDICAL RECORD, January 2, 1915, page 36.)

3. Pneumococcus Infection.—R. I. Cole states that it has been possible to produce serums of very high protective power against pneumococci of Type I and Type II. A method has been devised for the rapid determination of the organism in each case, and the corresponding serum is used. Usually 80 to 90 c.c. of the serum are injected intravenously, and this dose is repeated in twelve hours. Usually these doses are repeated on the following day, and this is continued so long as the patient's condition indicates that it is advisable. The treatment has so far been carried out in only a small series of cases of pneumonia due to organisms of Type I occurring in the Hospital of the Rockefeller Institute, and the number of cases is still much too small to enable the author to draw conclusions as to the efficacy of the serum from mortality statistics alone. In a small number of cases the results have been extremely encouraging, both as regards the effect on the clinical course and on the outcome. Stress is laid on the following observations: First, in a considerable number of the treated patients, the blood cultures, before beginning treatment, have been positive. In some of them the degree of general infection as indicated by the number of colonies per cubic centimeter was quite high. A high grade of general infection is of bad prognostic import. The two main conditions associated with the death of patients with pneumonia are the increasing invasion of the blood by pneumococci and the extension of the local lesion. In every treated case in which the culture from the blood was positive before the first injection of the serum, following one injection, and before the second one was made, the culture of the blood was negative and remained so. Second, it has been demonstrated that the process of recovery in pneumonia is associated with the appearance in the blood of substances which are able to protect mice against infection with pneumococci. Whereas in the untreated patients these substances appear only late in the disease, at or following the crisis, in treated cases their appearance is very appreciably earlier, usually shortly after treatment is begun.

4. Radium Therapy.—W. B. Chase concludes that (1) the destructive power of radium on cancer cells is well established. (2) The employment of radium in cancer is not in conflict with surgery, but both possess distinctive fields of usefulness, each having its limita-

tions; they are largely supplemental to each other, and there is ample opportunity for cooperation and reciprocity. (3) Large, operable malignant growths should be removed by the knife. (4) The analgesic power of radium is one of its most precious properties. (5) Want of confidence in radium arises from the use of low grades or spurious products, and from want of knowledge and skill in its application, together with the exaggerated, conflicting, and false reports so constantly current. (6) Postoperative radiation is of great usefulness and rapidly coming into professional use at home and abroad, being commended by prominent authorities, who not long since were unconvinced of its curative and palliative powers. (7) Crossfire application of radium increases its efficacy and aids by its multiple application in securing deeper penetration of large areas than by ordinary methods of application. (8) As in surgery so in the application of radium, disappointment is likely to follow too optimistic expectations of recovery. (9) In proportion as metastasis is present the chances of cure diminish, and in turn delayed diagnosis is often responsible for metastasis.

5. **Feeding the Newborn Infant.**—C. Herrman employs the following method: Six hours after delivery the baby is put to the breast and thereafter regularly every three hours during the day. It remains at the breast five minutes and is then given one and a half ounces of a 10 per cent. solution of lactose. This is usually continued for the first forty-eight hours. If the mother has an insufficient amount of breast milk, and no other mother in the ward is available for breast feeding, the supplemental feeding with a solution of lactose is continued for one or two days longer. The results of this method are a reduction in the average initial loss from eleven to six ounces; an increase in the percentage of cases regaining their birth weight after ten days, from 35 to 65 per cent; and no inanition fever.

7. **Decapsulation of the Kidney.**—R. R. Huggins believes that decapsulation and nephrotomy are indicated: (1) In toxic nephritis following acute poisoning by mercury or carbolic acid. (2) In nephritis following infection, especially the acute infectious diseases, such as scarlet fever, in which there is great edema, or in the presence of uremia; their use should be considered as soon as medical measures have been thoroughly tried without relief. This is true especially in young adults and children. (3) In severe hemorrhage complicating chronic nephritis, when the bleeding is practically limited to one side. In these cases a nephrotomy should be done to make sure of the exact cause of the hemorrhage. (4) They may be indicated for the relief of renal pain which sometimes occurs in the course of chronic nephritis. (5) They may be of value in uremia and anuria during the course of chronic nephritis, merely as an emergency measure. (6) In eclampsia, when the symptoms are due to faulty action of the kidney and improvement does not follow delivery of child. (7) Cases of movable kidney associated with albuminuric casts and hematuria, in which the urinary signs result from the trauma incident to the mobility, may be cured by decapsulation and fixation, but when coincident with chronic Bright's, only temporary good is effected.

1. **Prenatal Care.**—J. Whitridge Williams, in an analysis of 705 fetal deaths, states that syphilis is the most common etiological factor concerned in the production of death, presenting an incidence of 26.4 per cent. Toxemia, including eclampsia, nephritis, and occasional rare conditions, which is usually regarded as the condition par excellence which can be influenced by prenatal care, is the cause of only 6.5 per cent. of the deaths, and consequently is accountable for only one-fourth as many as syphilis. Notwithstanding most painstaking investigation the cause of death could not be satisfactorily explained in 127 cases, or 18 per cent. The death rate is nearly twice as high in the blacks as in the whites, 9.4 and 5.1 per cent. respectively, and equals or exceeds that of the whites in all but three categories, namely, toxemia, deformities, and placenta previa. Prenatal care is not merely a matter of a few visits by a nurse to the patient in her own home, but should consist in the coordination of the medical, nursing, and social-service resources of the hospital in the effort to obtain such treatment and supervision for the mother as will offer the greatest possible guarantee for the safe delivery of a normal child which can be kept healthy by maternal nursing.

7. **Atropine Treatment of Dysmenorrhea.**—E. Novak states that his experience with this method of treatment has been most encouraging. In the frequent cases of young unmarried women in whom pelvic examination is obviously undesirable, and who present the classical picture of spasmodic pain recurring with each menstruation, the atropine treatment is indicated without the preliminary of pelvic examination. The cases which respond most favorably are generally those in which the atropine has been pushed to the point of tolerance. The plan has been to commence the administration of the drug about two days before menstruation is expected to appear, and to continue its use until the second or third day of menstruation, depending on the usual duration of the pain. Patients differ in the degree of tolerance to the drug. Ordinarily about 1/100 grain is given three times a day, unless some pain appears, in which event, if there are no symptoms of atropine saturation, the doses may be given somewhat more frequently. Many patients complain of dryness of the throat, itching of the skin, and sometimes even disturbed accommodation, in which case it may be necessary to lessen the dosage somewhat.

9. **Amino-Acids in Blood and Spinal Fluid.**—A. W. M. Ellis, G. E. Cullen, and D. D. Van Slyke have found that: (1) The amino-acid nitrogen of the blood varies within certain definite limits (4.5 to 8.5 milligrams per 100 cubic centimeters) in different individuals. (2) A similar variation occurs in the same individual at different times. (3) The amino-acid nitrogen in the spinal fluid in different individuals, and also in the same individuals at different times, varies between approximately 2 and 4 cubic centimeters per 100. (4) The amino-acid nitrogen content of the blood in syphilitics varies with-

in exactly the same limits as in the blood of non-syphilitics. The amino-acid nitrogen content of neither the blood nor spinal fluid of a sphyilitic bears any relation to the Wassermann reaction. (5) The conclusion of Kaplan and of Kaplan and McClelland that in patients with syphilis the amino-acid nitrogen of the blood is diminished, and that such determinations may be used as a means of diagnosis is incorrect.

11. **Fractures of Inferior Maxilla.**—H. S. Dunning notes that the inferior maxillary bone on account of its position and shape is the most frequently fractured bone of the face and about tenth on the list of all bones of the body to be fractured. About 98 per cent. of all fractures of the body of the bone are compounded when there are teeth present. And thus it is the most frequent bone to suffer a compound fracture. The fracture of this bone becomes infected, on account of the fractures being compound, more than any other bone. The patient suffers great pain from injury to the inferior dental nerve and also from the inability to swallow, eat, drink, and cough. The fracture is about ten times as common in man as in woman. The most common age is between thirty and forty. The most frequent cause is a blow of the naked fist. A line of fracture is most often at the region of the bicuspids on the left side. Fractures of the lower jaw depend a great deal on the occlusion of the upper and lower teeth. Fractures of the condyles are rare, but are often followed by bony ankylosis. Fractures of the coronoid process are extremely rare and occur only when the zygomatic arch and the side of the face are severely crushed. Great care should be exercised in keeping the mouth clean in the treatment of fractures of the jaw. A cap splint or single-arch splint should be used whenever there are one or more strong teeth on either side of the line of fracture to which the splint may be cemented. The interdental splint or intermaxillary splint should be used only in children, in edentulous mouths, and in fractures posterior to the third molar when the upper and lower jaws cannot be wired together by means of Angle's wires and bands. The open operation or surgical wiring of the fractured ends of the bone is unnecessary and generally results in infection and necrosis. The inferior maxillary bone can be more accurately reduced and held in better coaptation than other bones, as direct force can be applied to it by means of appliances attached to the teeth. Non-union very rarely occurs and is generally due to faulty or delayed treatment. An *x*-ray picture should always be taken to ascertain the line of fracture, to discover the presence of impacted teeth, and to note any infections or abscess conditions at the apices of the teeth near the point of fracture.

1. **Pancreatitis.**—Sir Frederic Eve states that clinical experience bears out the conclusions that stasis and infection are the main elements in the causation of acute pancreatitis, and these are most commonly brought about by cholelithiasis. Occasionally acute pancreatitis may be due to the regurgitation of duodenal secretion. An acute pancreatic lesion which does not end fatally may terminate in chronic pancreatitis or in sclerosis. Like acute pancreatitis, the chronic form is closely related to cholelithiasis, especially to stones in the common duct, which would cause intermittent stasis of biliary and pancreatic secretion, and be associated with biliary infection. Gastroduodenitis and ulcers favor the occurrence of an ascending infection of the biliary duct and intermittent stasis may result from congestion at the papilla. Cancer of the head of the pancreas is in rare instances a cause of chronic pancreatitis. The author details the symptoms of acute pancreatitis based upon an analysis of twenty-four consecutive cases at the London Hospital and of sixteen cases reported by Dietrich. Over one-half of the patients had premonitory symptoms of varying intensity. These consisted of attacks of pain in the upper abdomen or occasionally over the abdomen generally. The symptoms of acute pancreatitis accord with the symptoms of the group of acute abdominal crises, and closely resemble those of the perforation of gastric and duodenal ulcer, of the gall-bladder, or of the appendix. Many cases have been mistaken for acute intestinal obstruction. The onset is sudden, with very severe pain in the epigastrium, persistent vomiting, usually constipation, tenderness, fulness, and resistance in the upper abdomen, and gradually increasing distention; the pulse is rapid and weak; the temperature lower than the pulse-rate, and not infrequently subnormal with collapse. The general condition of patients with acute pancreatitis is indicative of an acute toxemia. The Cammidge reaction is of no value in the diagnosis. Operation is indicated at the earliest possible moment. The procedure generally followed after opening the abdomen is to pack off the lower part of the peritoneal cavity with gauze, open the lesser cavity of the peritoneum through the gastrocolic omentum, and mop up any collection of serosanguineous or seropurulent fluid within it. The covering of the pancreas is divided, and blunt scarification made along its whole length, or over the part affected, sometimes only the head. Bleeding is stopped by underrunning vessels with catgut, or a gauze plug is fixed in position with catgut sutures. A drainage tube is left in. If there is a quantity of fluid in the peritoneum a drain should be inserted above the pubes. In those cases in which a collection of pus exists this should be drawn off by aspiration before the cavity is opened.

5. **Amputations in War Surgery.**—M. Fitzmaurice-Kelly calls attention to a method of amputation which he has suggested and which is now widely practised in some of the military hospitals in France. The method consists in a simple circular division of all the tissues, including the bones, at the same level, and that level the lowest possible. The skin is divided by a circular sweep, the muscles are divided at the level to which the skin retracts, and the bone is then sawed at the same level. The bleeding points are secured and tied, the nerves pulled down and cut short, and a dressing is then applied to the raw surface of the stump. The advantages claimed for the method are: (1) Economy of tissue. The amputation is performed at the lowest level at which a flap could be cut, or even lower, and all recoverable tissue is thus preserved. (2) It is applicable to otherwise hopeless cases, such as wounds or gangrene at the root of the limbs, and in these cases carries a much better prognosis than disarticulation at the hip or shoulder joint. (3) It is very rapidly done, and there is very little shock. (4) The surface from which septic absorption can occur is the least possible, and the drainage is free. (5) The nutrition of the stump is unimpaired; in this respect its advantage over a flap amputation is obvious. (6) It is so simple that it is said to be within the range of every one and not to need an experienced surgeon for its performance.

1. The Principles and Practice of the Localization of Foreign Bodies by *X*-Rays. Sir James Mackenzie Davidson.
2. Some Practical Hints on the Localization of Bullets and Shell Fragments. F. Hernaman-Johnson.
3. A Rapid Method of Localization by *X*-Rays. K. W. Mackenzie.
4. Acute Hemorrhagic Pancreatitis. With Remarks on the Etiology of Chronic Pancreatitis. Sir Frederic Eve.
5. Gray Hair and Disease Limited to the Nasolabial Area. G. Lenthal Cheatle.

1. X-Ray Localization of Foreign Bodies.—Sir James Mackenzie Davidson calls attention to the misleading character of the single radiograph with reference to the localization of foreign bodies. Whatever method is adopted the first essential is to have some means of determining the exact position of the point of emergence of *x*-rays from the tube in relation to the patient's body. The author describes a method which makes use of a specially constructed couch and of an arrangement of wires, the details of the entire apparatus being too complicated to be described in this place. There is used in addition a so-called cross-thread localizer which enables measurements to be made by reconstructing geometrically the conditions of the exposure. Among the surgical precautions to be adopted in dealing with foreign bodies, the author mentions the following: The patient should be placed in precisely the same position as he occupied at the time the *x*-ray photograph was taken. The surgeon should be very careful to ascertain the exact position of the foreign body which he proposes to remove. An important aid is the use of a probe with a telephonic attachment.

5. Gray Hair and Disease in the Nasolabial Area.—G. Lenthal Cheatle describes the case of a man a portion of whose moustache fell out for no determinable cause at the right hand extremity only. The part remained bald for about three months; when hairs reappeared they were gray, and that portion of his moustache has remained so, the rest being normal. Another instance is cited in which the hair is gray everywhere on the face except the central portion of the moustache. Cases of grayness of hair limited to the nasolabial fold are not exceptional. The author calls attention also to cases of rodent ulcer, in which the disease shows a tendency to become arrested at the vertical line which marks the internal limit of grayness. A syphilitic rash involving the upper lip tends to occupy the area that is not involved by rodent ulcer.

Tetanus.—Wolfsohn states that in all warfare tetanus becomes cumulative. In two military hospitals with which he is affiliated no less than twenty-nine cases of the disease were seen in five weeks. In almost every case the wounds were relatively extensive, undermined with pockets, and covered with a dirty coating. The average period of incubation was very brief—five to eight days. As might have been expected the mortality was frightful in comparison with certain favorable series published from time to time. Of the twenty-nine patients but two recovered! The two recoveries were examples of the long incubation period in which prognosis is almost favorable. That no treatment was spared is shown by the citations: Every subject but three received his due of antitoxin not only seasonably but in sufficient quantity and distribution. The results almost justified the belief that serum has possibilities for evil. One patient died within thirty-six hours, despite serum injections. By an "irony of fate" the two patients who recovered had received no serum. The author used magnesium sulphate intramuscularly in nine cases and saw no improvement whatever, yet concedes that this remedy was used in the two recovered cases. The author praises chloral in these fulminating cases, while antitoxin receives full credit as a prophylactic.

Anthrax (Splenic Fever) as a War Scourge.—Richter and his historiographical colleagues have long labored to show that this condition, now held in bounds, was in medieval and classical times a terrible scourge. This knowledge has not caused any reaction worth mentioning in the present war. The pestilence can readily be traced through history. It is spoken of in Exodus as deadly to mankind and livestock. A similar scourge is mentioned in the Iliad, and also by Seneca. The plague described by Thucydides harmonizes better with anthrax than with variola, typhus, and bubonic plague. This was also a war plague, as were several subsequent scourges. A careful perusal of the descriptions of Thucydides and subsequent narrators readily shows how much better the disease pictures adapt themselves to what we know today of anthrax than they do to other similar states. The probability of anthrax is associated throughout with a disease which attacks both mankind and domestic animals, and it is in war especially that such diseases should spread.

Russian Machine-Gun Bullet Extracted from the Bladder by Means of the Urethra.—Zondek relates the following case: A reservist, aged twenty-five, was hit last September by a missile, as above described, close to the orifice of the penis. He passed no urine for eighteen hours, passage painful, urine bloody. At the time the bullet could be felt in the penis, but five days later it was found to have escaped in some manner. The bladder and urinary excretion showed marked disturbances, including retention and frequent micturition. Upon examination by the author the bullet wound was found to be cicatrized; no visible opening of egress; urine common to that of hematuria. An *x*-ray picture showed the presence of the bullet, apparently just in front of the symphysis. Cystoscopy, however, showed the missile to be in the bladder. These projectiles are long, narrow, and pointed, and for their extraction the author devised a bullet-catcher especially adapted to seize an object of this sort. With this resource he was eventually able to extract the projectile with considerable difficulty but without permanent injury to the bladder.

Prognosis and Therapy of Abdominal Gunshot Wounds.—Rotter having studied a number of small series of these injuries finds mortalities as high as 80 per cent. This figure, however, is far behind the naked truth. The cases were treated in the field hospital. Let us now take the cases on the fighting line which were borne to the dressing stations and never reached the field hospital. Fifty-six soldiers died outright from their abdominal injuries who would, had they survived, have reached the hospital. If we add the fifty-six to the thirty-two who arrived at the latter we have a material of eighty-eight cases with seven recoveries and eighty-one deaths. Only here and there can we expect to save a life.

War Letters from a Military Hospital.—Klaussner continues to publish these documents which proceed from the various hospital stations, which are doubtless somewhat novel in warfare. Schlösser, who writes from the Ophthalmic Station, states that actual material of ocular lesions is not more cumulative than that seen in civic clinics. It is far otherwise, however, with wounds of the bony regions which communicate with the orbit. Eye lesions also complicate numerous conditions which

have little in common. Slight wounds of the globus are like those seen in civil practice with their menace of sympathetic ophthalmia. Severe wounds which lay bare in part the orbit may in theory readily be infected. Here we have the alternative of attempting to retain vision (or form an artificial eye stump) or of cleaning out the orbit. Müller, writing from the Odontological Station, states that civil and military practice in this field differs widely. Ordinary bullets cause comminution of the jaw bones, while shell fragments, besides causing the most horrible lesions of the soft parts, splinter teeth and jaws in all directions, while dirt is forced into the wounded area. These victims cannot reach a stationary hospital before the end of about a week, having meanwhile a simple retentive dressing. Everything is then found to be reeking with putrid pus. It must be owned that bandaging these wounds is open to question. Fixed dressings prevent drainage of saliva and wound secretion. A sort of light mask with windows should answer better. A very striking feature of these wounds is the favorable prognosis. Herzog, from the Otological Station, states that external violence is responsible for most injuries of the ears, especially detonation. The drumhead often ruptures if the subject is near to an exploding shell, and the apertures are very large, so that only a narrow margin of drum-head remains. Kattwinkel, from the Internal Station, reports the occurrence of heat-stroke and infectious enteritis (both very common). There was but little true dysentery. An epidemic of typhoid seems to have been jugulated by isolation, inoculation. Diseases incidental to cold and damp weather were very few, as were venereal diseases. In general the deaths were very few and the condition of the troops excellent.

Feeding the Civil Public in War Time.—In a document signed by numerous Munich physicians it is said that Germany is in no danger of starvation. Sea fish can be caught in abundance in the season; what is not eaten may be canned and preserved for reserve food. Some fish not commonly eaten can be utilized. Legumes which come from Russia no longer exist in Germany, but next spring will be cultivated in enormous quantities, including the soja bean. Hungary will also cultivate the legumes. Artificial fertilizer will be required. Vacant lots and unused spaces can be utilized for the cultivation of all the legumes. Rice can be obtained in great quantities from Italy and stored against need. Food chestnuts can be drawn upon for regular consumption. Maize, like legumes, can be made to grow in abundance and more oats can be raised. Rolls can be made of rye-meal. People must be taught food values so that the acquired demand for milk, eggs, and meat may be turned in the direction of the cereals, potatoes, legumes, etc. Children especially should be taught to eat fruit, salads, vegetables, etc. Indulgence in alcohol should be diminished, because alcoholic beverages are relatively costly in comparison with the raw materials from which they are made. It makes a German soldier very bitter to think of himself half frozen in a trench while the stay-at-homes are sitting contentedly in a comfortable public-house. The stay-at-homes should therefore regard self-denial as a form of patriotism.

Forensic Activities of the Military Surgeon.—Reckzeh states that this province of military medicine must be regarded as of equal significance with prophylaxis and cure. The rights of the soldier and those of the fatherland must be alike respected. A parallel condition is seen in life insurance. Medical opinions in a campaign must be brief and to the point. The first thing to be considered is the declaration of the soldier in regard to fitness for military service, along with the objective conditions (characterized briefly as normal, good, etc.) The two are then compared and the opinion must be so couched as to be intelligible to the layman. At times some examination may be requisite. The fitness for duty must depend at times on what the duty is. There is on the part of the soldier a certain tendency to exaggeration, simulation, and dissimulation, but in the German troops this tendency is seldom in evidence. Under simulation comes exaggeration of past sicknesses, false statements as to their causation, or statements to the effect that old ailments are being aggravated by military duty. The soldier of this type would like to be judged incapable of shooting well or of some other form of inefficiency, and his ailments will be of the sort which will give this impression to the exclusion of others which would be less injurious to him as a soldier. The claimant does not so much fabricate as overvalue certain immaterial symptoms. These men are often nervous and hypochondriacal by nature, and the army would perhaps be better off without them. Simulators are best examined privately and surprised into contradictions or confessions. A man who simulates deafness will readily deny that he hears a whisper or other test because he is on his guard. But afterward when told from behind to "face about" he obeys the order. Ruses of this sort are common in the detection of simulation.

Cystin Calculi and Cystinuria.—Neumann states that 170 cases of these conditions have now been reported. Of late years interest in cystin has notably increased. The author has seen two cases which he reports in great detail. The first case was a renal calculus. Family and personal history of the twenty-four-year-old girl was good. Up to a certain day her health had been perfect and the urine normal. Within two months the entire disease-picture developed. Upon admission she presented a high degree of pallor. Chest, abdomen, and general nutrition without finds. A tumor was palpable at the site of the right kidney with patient in left lateral decubitus.. Left kidney seemed normal. Urine contained cystin crystals and blood corpuscles. A part of the diagnosis was therefore readily made. Under pyelography the *x*-ray revealed the pressure of a stone in the kidney pelvis. Pyelotomy then revealed the presence of cystin calculi. These were removed, everything healing cleanly. The patient, however, showed no corresponding improvement. The kidney which had shown numerous little points of suppuration at the operation continued to give trouble and its fellow also began to show symptoms. The *x*-ray showed no calculi anywhere, nor did the urine contain anything abnormal save a few cystin crystals. An attempt was made to determine the amount of cystin secreted, but the maximum values found were not significant. It was easier to determine the number of crystals in the sediment of each portion of urine passed, in the hope of causing them to vanish. Treatment consisted of bed rest, milk diet, bicarbonate of soda. Cystinuria was greatly benefited, but there was a possibility that other kinds of stone could develop.

The Histodiagnosis of Chronic Endometritis. — Vincenzo Vannelli concludes that this condition is the result of an inflammation involving the epithelium of the uterine mucosa, the chorion, the glandular epithelium, the blood vessels, and the mesometrium. Of considerable diagnostic value is the detection of plasma cells. Normally the uterine epithelium does not secrete glycogen, the detection of which, therefore, indicates an inflammatory change in the endometrium.—*Giornale Internazionale delle Scienze Mediche.*

Insurance Medicine.

Medical Examinations for Life Insurance.—Dr. Cuthbert Powell, in a paper given before the Boulder County Medical Society, April 23, outlined the attitude that should be taken by the medical profession toward insurance work. In all of our American companies the selection of risks by medical examiners has been practised since their inception. Recent figures gave 76,500 appointments as medical examiners for five of the larger life companies, and $347,810 was paid by one of these companies in 1913 to its examiners in the domestic field alone. When one considers that in the United States alone there are about 260 life companies, all employing medical men in the selection of applicants for insurance, one begins to realize what a tremendous part these companies play in augmenting the income of members of the profession, and the right they have to expect and receive only the finest type of work from their medical examiners. Too little consideration, he says, has been given to this phase of professional duty; and the training for it should be given at the medical colleges. It has been taken for granted that no special knowledge was required to enable one to examine properly an applicant for life insurance. This is a mistake and one which should be speedily corrected. In ordinary practice the presumption of ill health is uppermost; in life insurance work the applicant is presumptively sound. In the one case the physician starts out with a known or probable abnormal, in the other with a presumptive normal. His mental attitude is thus reversed, and the importance of a neglected branch of study, that of a normal body, is strongly emphasized. Speaking broadly, nine out of ten patients are diseased, and nine out of ten "applicants" are healthy. No physician can honorably retain an appointment as examiner for a life company unless he is willing and able to devote sufficient time and energy to the proper performance of the special duty required of him; it is the duty of our medical colleges to equip their students with sufficient knowledge to properly perform this part of their professional vocation, since it is from this work that the first income is received, long before the opportunity arrives to perform and receive compensation for major operations. That physicians generally are either incompetent or extremely careless in the making of life insurance examinations is shown by the fact that out of a certain hundred examinations fifty-four, or a little more than half, were completely recorded, requiring the necessity of obtaining additional information in order to complete the reports, and a delay in time which means much to both agent and applicant. Pecuniary loss may be suffered by widow and children by reason of the applicant's death pending information required of the medical examiner. The medical examiner, too, has his problems, and the higher the type of man the greater the problem. The examiner must remember that he is employed by the company and not by the applicant or agent. Any information obtained during the course of the examination belongs always to the company, and should not be withheld even though facts appear thereon which are detrimental to the applicant. The examiner receives his fee for all examinations whether a policy is issued or not; he must not be influenced by either agent or applicant. No matter how carefully the history may be taken or how thoroughly the physical examination is made, unless the questions on the examiner's report are answered in words or figures, the medical director cannot pass upon the applicant's insurability; dashes, ditto marks, and blank spaces are not accepted as answers to questions. All applicants for insurance are passed upon by at least two medical men, the local examiner and the medical director. The local examiner does not accept or reject an applicant, but his report should convey to the medical director such knowledge that he may act intelligently upon it. Some companies employ a medical referee, whose duty it is to obtain such additional information as may be necessary from the examiner to enable the director to pass upon the applicant's insurability, and also to recommend as examiners physicians in his territory where vacancies exist. It occurs that applicants who are passed as first-class risks by the medical examiner are rejected by the medical director, due to the fact that he obtains knowledge of the risks about which the examiner knows nothing. Naturally the examiner desires the reasons for such action. The medical department is in possession of special knowledge of mortality statistics and rules of selection not accessible to an examiner, and has at its command important sources of confidential information and means of special inquiry. The examiners' relation to the agent is sometimes a vexatious problem, but it is always well to consider the point of view of the agent, as the most of them are honest, ambitious men and women doing hard and often disappointing work. As examiners, physicians can do much to aid them by occasionally inconveniencing themselves to make quick examinations. Honesty, absolute incorruptibility, and a deep sense of moral obligation, which are the best vouchers for moral courage, are required of the examining physicians. *Denver Medical Times*. October 1914.

Status of the Medical Director in Courts.—Blackburn considers the medical directors as the "Biological Engineers" of life insurance, as essential to ultimate success as the agency department is essential to immediate results. Medical directors and actuaries combine the knowledge and experience of the relations of normal and abnormal man with the mathematics of probabilities and averages. They resolve the doctrine of diseases, their courses and modes of occurrence into statistics sufficiently accurate to warrant the company guaranteeing with absolute certainty the ultimate fulfillment of its contract obligations. The medical director is the credit man of the business and the actuary is its comptroller. The courts, however, have not dealt with the medical department as frequently as with the agency department because the medical department is intermediate. The agency department is initial. The executive department is final. On these two departments hang most of the law of life insurance.—"The Medical Department in Court," American Life Convention.

Medical Section of the American Life Convention.—The fifth midyear meeting of this very active association will be held at the French Lick Hotel, French Lick Springs, Indiana, on March 3, 4, and 5, 1915, under the presidency of Dr. Whitfield Harral. The secretary is Dr. F. L. B. Jenney, 168 North Michigan Avenue, Chicago, Ill.

Book Reviews.

Précis de Chirurgie de Guerre. Par E. Delorme, Medecin Inspecteur General de l'Armée, Membre de l'Académie de Médecine, Membre et ancien Président de la Societé de Chirurgie, grand officier de la Légion d'Honneur. Price, 4 fr. 50. Paris: Masson et Cie, 1914.

This excellent little book, which, as the author tells us, was not thought of until the unexpected declaration of war by Germany made evident the necessity of some manual of instruction for the civilian physician suddenly confronted with military medical problems, is one that answers its purpose capitally. Though written under pressure, begun at Paris during the first days of mobilization, interrupted repeatedly by the engrossing calls upon the time of a medical inspector general, taken up again at odd times, during the noonday rest, during the intervals of inspection, and finished in the small hours of the night after fatiguing work in the field and the hospital, the book shows no signs of haste. It is, of course, no formal treatise, but merely a practical manual instructing the volunteer surgeon in his new duties with the army on the battle line or in camp, warning him of the problems he will be called upon to meet, and telling him what to do and what to avoid. The book is of portable size and shape, clearly printed, and neatly bound. It might be studied with profit by medical officers of the National Guard as well as by the lieutenants of the medical reserve corps of the U. S. Army.

Operative Surgery: The Head and Neck, the Thorax, and the Abdomen. By Edward H. Taylor, M.D., B.S. (Dub. Univ.), F.R.C.S.I. Professor of Surgery in the University of Dublin, Surgeon to Sir Patrick Dun's Hospital Quarto, 524 pages; illustrated with 300 figures from original drawings, many printed in colors. Price, $9.00 net. New York: William Wood & Company, 1914.

In this work a different plan has been followed from that of the ordinary operative surgery, where the attempt is usually made to cover the whole field. Taylor has confined his attention to the surgery of the head, neck, thorax, and abdomen, and even here has made no attempt to cover all the operative procedures that *may* be employed but has included those which the general surgeon is most likely to be called upon to perform; while of the almost innumerable methods of performing some operations he has selected and described the technique that he has himself found most satisfactory. By thus eliminating the descriptions of a host of rarely used methods, usually transplanted bodily from one text-book to another, he has been enabled to devote adequate space to more important operations and to incorporate a profusion of magnificent illustrations and still keep the size of the book within reasonable bounds. While occasionally, as, for example, in the case of inguinal hernia or gastroenterostomy, several methods of performing an operation are given, frequently but one is described, thus compelling the reader to acquire a thorough grasp of the important principles and avoiding the danger of confusion of ideas so often resulting from attempts at abbreviated descriptions of numerous slight differences in technique in operations designed to accomplish the same purpose.

The first section is devoted to surgical technique, including the questions of sterilization, preparation of patient, operator, and assistants, ligatures and suture materials, drainage and drainge materials, the choice and methods of administering anesthetics, etc., and it is remarkable how well the essentials have been covered in the 30 pages allotted to this section. The remainder of the book is devoted to the surgery of the regions indicated in the title. The principal operations on the head and neck are well covered, the author being assisted in the preparation of the sections on the larynx by Sir Robert Woods, and in those on the mastoid and maxillary sinus by Mr. T. O. Graham. In the section on the thorax Taylor has taken up the operative surgery of benign and malignant tumors of the breast, acute and chronic empyema, and the treatment of pericardial effusions. It seems unfortunate that this section was not amplified to include at least something on the surgery of the lung, for in recent years considerable progress has been made in this field.

The section on the abdomen must be considered a masterpiece. The keen summarizing of pathology and indications for operation, the choice of operation and concise description of technique, the wide range of valuable comments suitable to the individual subject, the remarkable illustrations—all these not only deserve but compel admiration. It is hard to single out any part of this section as being more worthy of special notice than another; but the unusually full treatment of colectomy, with the author's comments and the particularly fine illustrations showing, among other things, the course and destination of the lymphatics and the proper lines of incision of the mesentery in order to preserve the blood supply in cases of excision of various portions of the large intestine, should appeal to the expert as well as to the beginner in the practice of surgery. To round out this section the technique of hysterectomy should be given, for in the country and even in the larger centers a large proportion of such operations are done by the general surgeon. The author gives credit to Mr. Adams McConnell and Mr. R. A. Stoney for aid in the preparation of parts of this section.

The index is remarkably complete, especially for a first edition and on the whole we have seldom had the pleasure of reviewing a book that came so near to the ideal in its aims and achievements.

A Practical Medical Dictionary of Words Used in Medicine with Their Derivation and Pronunciation, including Dental, Veterinary, Chemical, Botanical, Electrical, Life Insurance, and Other Special Terms; Anatomical Tables of the Titles in General Use, and Those Sanctioned by the Basle Anatomical Convention; Pharmaceutical Preparations, Official in the U. S. and British Pharmacopœias, and Contained in the National Formulary; Chemical and Therapeutic Information as to Mineral Springs of America and Europe, and Comprehensive Lists of Synonyms. By Thomas Lathrop Stedman, A.M., M.D., Editor of the "Twentieth Century Practice of Medicine," of the "Reference Handbook of the Medical Sciences," and of the "Medical Record." Third Revised Edition. Illustrated. Price, $5.00 net. New York: William Wood & Company, 1914.

Since 1911 there have appeared three editions of this work, which has grown from the original 1000 pages to 1059 pages. This increase in size has been necessitated not only by the inevitable accretions to an already unwieldly medical vocabulary, but also by the revision and amplification of former definitions. This work is not a mere compilation, but shows on almost every page the results of sound judgment in the selection of words where alternative terms are in use, in the omission of obsolete expressions, and in the inclusion of new words which have earned a place in the medical vocabulary. The value of a medical dictionary to the undergraduate student is to be gauged largely by the clearness of its definitions, the ease of reference, and the indication of the preferable term or terms to be chosen when several are in use. To the advanced student and general medical reader the value of a medical dictionary is to be determined largely by the new words that it defines. The needs of both classes of readers are apparently well supplied by this volume.

Lehrbuch der Oesophagoskopie. Von Prof. Dr. Hugo Starck. II Neubearbeitete Auflage. Price, 9 M. Würzburg: Curt Kabitzsch Verlag, 1914.

Prof. Starck has rewritten the entire first part of his text-book, which is devoted to technique and to the instruments. He says that the theory and practice of esophagoscopy has advanced very little since the von Mikulicz era—the date of the previous edition of a decade ago.

A Manual of Diseases of the Nose, Throat, and Ear. By E. B. Gleason, M.D., LL.D., Professor of Otology in the Medico-Chirurgical College; Aurist to the Medico-Chirurgical Hospital; Surgeon-in-Charge of the Nose, Throat, and Ear Department of the Northern Dispensary; Formerly one of the Laryngologists to the Philadelphia Hospital. Illustrated. Third edition, thoroughly Revised. Price $2.50. Philadelphia and London: W. B. Saunders Company, 1914.

Students and general practitioners will find in this volume the essential facts of rhinology, laryngology and otology, correctly stated. Special attention is given to methods of examination, diagnosis, and treatment; operations are clearly described, and where the methods of operation are numerous, the author has selected those which his experience has led him to believe will prove most useful to the readers for whom this book is intended. The language of many of the prescriptions is capable of improvement; books intended for students should be immaculate in this respect.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 17, 1914.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

Blood Transfusions, Indications and Results, Based on Observations of 212 Transfusions.—Dr. R. OTTENBERG and Dr. E. LIBMAN presented this communication, which was read by Dr. Libman. He stated that the real value of transfusions and the real indications for it were becoming better understood as a result of the large number of transfusions that had been done since Crile had introduced direct transfusion. They had studied 212 transfusions in 189 cases, chiefly through the kindness of the attending staff of Mount Sinai Hospital, New York. Of these 85 cases, or 45 per cent., were successful in that the condition of the patient was greatly improved, and 42, or 20 per cent., were actually life-saving. The cases might be classified as follows: (1) Successful cases, to which belonged those in which the prognosis was extremely bad and transfusions saved life (some of these subsequently recovered, while in others the original underlying disease continued) and those cases which recovered in which the prognosis before transfusion was not desperate. (2) Unsuccessful cases, of which there were 104. These cases might be classified into three groups: (1) Cases in which there was temporary improvement following transfusion, with death later from continuation of the original disease; (2) cases which died of some disease necessarily fatal and in which transfusion could not have been expected to do much good; (3) cases in which transfusion did little or no good, although from the nature of the disease a good result might have been possible. The most interesting cases were those in which transfusion was life-saving and these were almost all cases of hemorrhage either from operation, disease, or hemorrhagic diathesis. Some of them were also cases of grave chronic anemia or poisoning. The speaker then discussed the special indications for transfusion under the following headings: 1. Transfusion for simple hemorrhage, (*a*) gastric and duodenal ulcer, (*b*) dysentery, (*c*) typhoid hemorrhage, (*d*) ectopic hemorrhage. 2. Transfusion in connection with surgical operations, (*a*) preliminary to operation, (*b*) for postoperative shock, and (*c*) for shock. 3. Transfusions for the cure of hemorrhagic conditions, (*a*) purpura hemorrhagica, (*b*) hemophilia, (*c*) hemorrhages secondary to blood diseases, severe infectious diseases, and jaundice. 4. Transfusions for blood diseases, (*a*) pernicious anemia, (*b*) leucemia. 5. Transfusions for infections, (*a*) infections with pyogenic organisms, (*b*) infective endocarditis. 6. Transfusions for intoxications, (*a*) acute poisonings, (*b*) diabetic coma. 7. Transfusions for debilitated conditions, (*a*) cancer, (*b*) malnutrition, (*c*) simple anemia. In the cases of hemorrhage from gastric or duodenal ulcer the results were exceedingly good; although all of the patients were in a desperate condition at the time of the transfusion, 12 of the 14 recovered. In dysentery, on the other hand, the results were rather poor, because, as might have been expected, the transfusion exerted very little influence on the course of the dysentery itself. In typhoid fever the results were exceedingly encouraging. Among seven transfusions for typhoid hemorrhage, four were successful in relieving the immediate symptoms of hemorrhage. Two transfusions in protracted cases of typhoid fever exerted a very beneficial effect on the course of the typhoid itself, and the authors recommended that in typhoid fever cases, at the first indication of blood in the stools, preparations be made so that a transfusion could be done at short notice if necessary, and that in protracted cases of typhoid state transfusion should be tried as a reviving agent on the patient. Possibly such transfusions would be more advantageous if a donor who had recovered from typhoid or who had been immunized could be used. In three cases of ectopic pregnancy seen by the authors transfusion was life saving. Among the most satisfactory transfusions in the whole series were some of those done preliminary to operation in patients whose desperate condition would otherwise have contraindicated any other operation. There were 23 such preoperative transfusions, and in 13 of them the result was decisive and the patients recovered. In shock, on the other hand, the results were very disappointing. The authors thought, however, that if the shock could have been foreseen so that the transfusion could have been done immediately, instead of after several hours' delay in obtaining a donor, the results might have been better. Perhaps the best results in the series of cases were those in the group of hemorrhagic conditions. These the authors discussed under three heads—purpura hemorrhagica, hereditary hemophilia, and symptomatic hemorrhagic diathesis. Of purpura hemorrhagica there were nine cases, all very severe, as no one had yet advocated doing transfusion in the milder cases of this disease. Of the nine cases, six recovered completely and one left the hospital greatly improved. The prompt cessation of the hemorrhage in most cases was very striking. After speculating as to what effect the blood transfusion might have on this disease the authors pointed out that it was probably not due to restored coagulability (as it was in hemophilia) because in most cases of purpura, the coagulability of the blood was not impaired. The two fatal cases of purpura hemorrhagica formed a peculiar group in that they were both cases of postpartum purpura hemorrhagica in which the ordinary kinds of bacterial infection could be excluded. They suggested that possibly this was a separate type of disease with a pathogenesis different from that of the other cases. In hemophilia the transfusion had an almost specific effect. In five of the six cases transfused the hemorrhage stopped promptly and the coagulation property of the blood became practically normal. In the cases that were followed for some period of time, however, the deficient coagulability always returned after some weeks or months. The authors suggested that every individual known to have hemophilia ought to have at his command several persons whose blood, by previous tests, was known to be compatible with his own. Whenever serious hemorrhage occurred prompt transfusion should be done. Besides this a small intravenous injection (25-50 c.c.) of whole blood should be given to such persons regularly at intervals long enough to have some continued effect. It was possible that if this was done the hemorrhage could be prevented and the majority of hemophiliacs able to lead a life of normal duration. In discussing the value of Weil's serum treatment in hemorrhagic diseases, Dr. Libman and Dr. Ottenberg were not in entire accord, though they believed that the serum treatment deserved a further trial. In almost all of the 35 cases in which transfusion was done for hemorrhagic disease serum treatment had been tried out thoroughly before the transfusion and had had no effect. In various types of hemorrhagic disease secondary to other conditions, in general transfusion helped to check hemorrhage, but only did so permanently if the original condition could be relieved. In cholemic hemorrhage the results were rather disappointing; only one of the seven cases recovered. They suggested that in these conditions the blood and the viscera were so badly damaged that only very large, and possibly repeated transfusions, so as to replace a very large part of the patient's own blood, would be effective. Of the 24 cases of pernicious anemia studied, 13 underwent more or less prolonged intermissions immediately following the transfusion. The cases which underwent remissions were generally those of longer duration than the ones that failed to undergo remission, and this suggested that there were two types of pernicious anemia; one a type with a rather definite onset and reaching a severe grade of anemia within three to six months, in which transfusion did little good; the other, a type with a less definite onset and slower progress, which tended to undergo remission spontaneously and in which new remissions could be brought about by transfusion. It seemed wise to do a large enough transfusion to overcome the anemia to a considerable extent because this tended to overcome the vicious circle caused by apparent degeneration resulting from the anemia itself. Nevertheless remissions sometimes occurred after small transfusions. The effect of the transfusion on the general condition of the patient was remarkable; the fever usually disappeared, and the appetite returned, although apparently the hydrochloric acid did not return to the gastric secretion. In regard to pernicious anemia, the authors concluded that transfusion was the best remedy and that though it never cured it led to remission in about one-half the cases. They recommended that if the first transfusion failed to bring about a remission, one should be tried from a different donor. With regard to splenectomy in pernicious anemia they had seen two cases, in one of which it was

very successful; in the other it was not. They believed that splenectomy had about the same effect as transfusion; namely, it brought about a remission, and judging from their experience up to date it should be reserved as a final method of producing remission when transfusion would no longer do so. In leucemia, the results were interesting. In myelogenous leucemia and acute lymphatic leucemia transfusion was without effect, but in four or five cases of chronic lymphatic leucemia transfusion was followed by a remarkable remission in which the blood picture returned temporarily to normal. The ultimate outcome, of course, was not affected. In bacterial infections, transfusion was of value only so far as it restored the general resistance of the patient. In cases of acute infection with pyogenic organisms, of which the authors reported ten cases, transfusion was of much value; but in protracted cases, particularly those of pyemia, transfusion sometimes produced remarkably brilliant results. In subacute bacterial endocarditis transfusion was of great value in combating the anemia and the general weakened condition. The authors suggested that in acute infectious diseases, particularly those in which serum immunity had yet to be demonstrated, transfusions be done from donors who had recovered and were therefore immune. This should be tried in malignant cases of the exanthemata. In gas poisoning transfusion was almost a specific treatment and should be accompanied by phlebotomy. In diabetic coma it was useless. After discussing certain technical questions affecting the indications for transfusion the authors pointed out that by careful performance of the tests for hemolysis and agglutination of either donor's or patient's blood by the other, the danger of fatal accidents could be absolutely excluded. They had had no such accidents in any of their cases in which this difficulty was excluded, but they had had three accidents in cases in which it was not. The danger of doing too large a transfusion was considerable, especially in cases in which the heart action was already impaired. The amount of blood which should be transfused should be carefully calculated and then strictly adhered to. It was wise before transfusion to have the donor sign a legal form relieving the patient and the surgeon from liability. The donor should receive fluids freely during the transfusion, but whiskey should be avoided as it seemed to cause vomiting when the patients became anemic. After discussing the various methods of doing transfusion, the authors decided that the syringe method was at present the best, since it was simple, did not injure the vein, and could be repeated as often as necessary on the same patient.

Treatment of Pernicious Anemia by Transfusion.—Dr. E. LINDEMAN presented this communication. He stated that to him the most typical feature of pernicious anemia was its variable and capricious course. The variability of the symptoms was so great that doubt as to the accuracy of the diagnosis was frequently felt. Most of the cases in his experience of the atypical type had proved later to be the pernicious anemia of Addison. Because of the capricious course of the disease one must ever be guarded in the presentation of any form of therapy lest one attribute to the therapy that which rightly belonged to the natural course of the disease itself. While in a number of cases a favorable change occurred spontaneously, only too frequently did death occur while awaiting the favorable moment for improvement. Transfusion had been practised for a number of years and the results were often strikingly brilliant, sometimes only temporary, and sometimes indifferent and even poor. In the writer's opinion the reason for this variable response was due in part to the extent and seat of the pathological invasion and in some cases to the incompatibility of the blood introduced. It would be entertaining to relate a series of dramatic successes in the treatment of pernicious anemia by transfusion, but for study a series of cases that did not respond well to any form of therapy including transfusion would prove more profitable. Splenectomy in pernicious anemia was not an accidental thought but was arrived at through rather laborious study and logical reasoning. Dr. Lindeman outlined the experimental work in reference to toluolendiamin poisining in animals and stated that the observers making these experiments concluded that toluolendiamin was a blood poison for dogs, powerful *in vivo*, but powerless *in vitro*. The poison alone did not affect the red blood corpuscles, but the hemolysis and icterus were influenced by the spleen. They believed the spleen took out the decomposition products of the red blood corpuscles and passed them on to the liver through the portal vein. The material for building bile pigment was over-abundant and the liver made an excessive amount of concentrated bile. The result was stasis and resorption causing icterus. Toluolendiamin was a hemolytic substance in the sense that it only injured the red blood corpuscles and did not completely destroy them. The spleen dissolved the injured red blood corpuscles and thereby subjected the liver to increased metabolism of blood pigment. The hemolysis in chronic toluolendiamin poisoning ran parallel with fatty changes in the liver and was benefited by splenectomy. In acute poisoning, no fatty change was found in the liver and splenectomy had no influence. Joannovics and Pick concluded that in chronic toluolendiamin poisoning after splenectomy there was a reduction in the building of higher unsaturated fatty acids in the liver. Here one found the first references to the spleen exerting some influence in fatty metabolism. The experimental work of Myerstein in regard to the protective bodies in cholesterin and of Eppinger showing that urobilin was greatly reduced after splenectomy led to the conclusion that in the absence of the spleen blood destruction was diminished. Pearce found that after splenectomy the resistance of the red blood corpuscles was increased and that this increased resistance depended upon the corpuscles and not the serum; however, there was an increase in the antihemolytic property of the serum. Splenectomy itself produced an anemia, which reached its height in from three to six weeks, and a leucocytosis. The repair of the anemia was longer in splenectomized than in normal animals, according to the experiments of Krumbhaar and Musser. In pernicious anemia the total fats were increased from 40 to 60 per cent., while cholesterin and cholesterin ester were decreased and the iodine combining power had from two to three times the normal value. Where hemoglobin and icterus occurred in a number of diseases, this relationship of the lipoid and fatty acid content of the blood obtained. King said that the occurrence of these acids was closely related to the activity of the spleen, since the removal of the spleen lessened their value in the blood and greatly benefited their hemolytic condition. These conclusions the author showed were well borne out clinically. In the literature about 35 cases of splenectomy had been reported. He had had under observation six cases of splenectomy with transfusion for pernicious anemia which he reported in full, and from a close study of these and some thirty other cases he concluded as follows: (1) Splenectomy played an important part in the course of events in this disease. (2) The removal of the spleen reduced the blood destruction percentually. (3) The extreme blood crises did not occur after splenectomy. (4) Splenectomy did not cure the disease; the patient still maintained the blood picture of a primary anemia, though clinically normal. (5) Considering the course of the disease the procedure was entirely justifiable. (6) Cases should be selected carefully and those showing petechia, hemorrhage, mental disturbances, and marked cord disturbances should be considered unfavorable to this procedure. Cases in which the vital staining could not be demonstrated belonged to the unfavorable group. (7) The patient should be transfused before splenectomy; he must not be allowed to make the blood himself. In many cases he could, but even if he could he should not be permitted to do so. By blood transfusion the bone marrow function was conserved for the vital need of the patient in the future.

Dr. MORRIS MANGES said that to those who had listened to what had been said on the subject of blood transfusion it seemed like a revelation of the value of this work, and he desired to emphasize the importance of this kind of work as he felt confident that five or six years hence the field for transfusion would be larger. There was much to be learned in making the indications more definite. The failures which had been so candidly reported were small when compared with the striking results obtained by transfusion. He had never seen a case in which transfusion had done so much as in the one case of typhoid fever referred to in which the primary attack lasted seventy-eight days. Without the transfusions this case would have been shorter and fatal. The first transfusion was done on the thirty-eighth day when the patient had had a third hemorrhage and was in a desperate condition. The transfusion checked the hemorrhage and the patient went on with the disease. On the sixty-sixth day

the blood culture showed that typhoid bacilli were still present and the condition of the patient was as bad as could be conceived and petechæ were abundant. A second transfusion was then done and within six days the patient was convalescent; this showed what transfusion could do. Dr. Manges said he was glad the point had been made with regard to the existence of fever due to anemia. One young woman, 26 years of age, was in a deplorable condition from metrorrhagia, the hemoglobin being 26 per cent. and the red blood corpuscles, 2,000,000. She did not have a sloughing fibroid or any other discernible condition to cause fever. There was a negative blood culture. In spite of all the negative findings she had a continuous fever of about 102-103° F. for a week after admission. By that time consent was obtained for a transfusion when the hemoglobin was 16 per cent. and the red blood cells were as low as 1,500,000. The transfusion raised the hemoglobin to 48 per cent. and the bleeding at once ceased. Likewise the fever disappeared. Neither returned and the patient made an uneventful recovery.

Dr. Willy Meyer said that it was a pleasure to know that blood transfusion had now reached a practical stage. In the employment of the older method and using the ingenious cannulas of Crile, Elsberg, Soresi, and Levine, one did not know just the amount of blood that the patient was getting, and the operation itself was rather cumbersome. The procedure worked out by Tuffier and Carrel, to make use of the recipient's saphenous vein brought some improvement, but not with reference to the question whether the patient was getting just what he needed. The Lindeman method counted a great step forward. They could now see what they were doing and were able to gauge the amount of blood to be transfused. Besides the vein of both patients was punctured, if necessary, repeatedly; cutting was abolished, and from the cosmetic point of view this was a great gain. Regarding pernicious anemia, he had done transfusion in two patients thus afflicted with marked temporary improvement. Perhaps the life of both might have been saved had splenectomy been added and the transfusions continued. It certainly was wonderful how this important chapter of diseases of the blood had become a "borderland" in the last years. Dr. Meyer said he wished to say a good word for the cutaneous injection of human blood serum in hemophyliacs and persons suffering from chronic jaundice. In both the dreaded secondary hemorrhage could often be well overcome by prophylactic repeated injections before operation. If done later, when bleeding had started, this treatment had hardly ever been effectual. This kind of preparation was simpler than transfusion, but the latter was preferable in case the patient was also rather anemic.

Dr. Eugene H. Pool said that his experience with transfusion was rather limited but possibly of some interest in the present discussion. When Crile and Carrel published their first articles, he became enthusiastic over end-to-end suture. McClure and he had reported twelve transfusions by this method with variable results (*Annals of Surgery*, Oct., 1910, LII, 433). He also tried the glass cannula and the Elsberg cannula. However, about eighteen months ago in spite of his enthusiasm for end-to-end suture the superiority of the Lindeman method over all others which he had tried or seen used became evident to him. At that time a boy was brought to the House of Relief with leg mangled; he presented profound anemia from loss of blood following accident. The parents refused permission to amputate for five days when both the crushed leg and the other leg were badly infected. A few days after the amputation the boy was practically moribund. He was so weak that a transfusion by a method which entailed much manipulation for a considerable time did not seem to be warranted. Dr. Pool therefore asked Dr. Lindeman to use his method. The veins in the boy and in the father, who was extremely fat, could not be seen. Nevertheless in an incredibly short time Dr. Lindeman inserted the needles and completed a transfusion. The boy was revived and rapid recovery resulted. A few months later they employed the method successfully in a case of extreme jaundice which presented marked hemorrhage following removal of stone from common duct (*Annals of Surgery*, Vol. LX, 1914, p. 7683). That the success of the method was not due simply to Dr. Lindeman's personal facility was attested by the fact that since then he himself had adopted the method exclusively and had used it in about 10 cases without much difficulty. In regard to the uses of transfusion, he emphasized its value in hemorrhage with jaundice; in this it might be well to use it as a prophylactic measure. He also emphasized its value as an ante-operative procedure in cases of extreme anemia.

Dr. Richard Lewisohn said that Dr. Lindeman's method certainly meant a step forward, but he did not agree with Dr. Willy Meyer that it was the best possible method; it remained to be seen whether a better and a simpler one could be found. In order to do Lindeman's method properly it required four persons. The great advantage compared with the older methods (anastomosis of artery to vein or vein to vein) was that one knew the amount of blood transfused, but one should have a method that could be practised with less assistance and greater ease. The speaker said that he had tried to mix anticoagulating substances with the blood to simplify the technique of transfusion. Hirudin and sodium citrate seemed to be substances applicable in this direction. Engelmann of Germany had used 0.3 grams of hirudin in twelve cases of eclampsia without any ill effect. To prevent the coagulation of 1,000 c.c. of blood (the usual amount used in blood transfusion) 0.1 gram of hirudin was needed. The speaker had tested out hirudin in a series of animal experiments and when he found no ill effects he injected 0.1 gram of hirudin into a patient suffering from inoperable cancer. The effects of this injection were so alarming that he certainly would not use it again. Sodium citrate, however, seemed to be very promising for this purpose.

Dr. William A. Downes said he wished to say a word in corroboration of what Dr. Lindeman had said in regard to splenectomy plus transfusion in pernicious anemia. Five of the cases whose histories were given by Dr. Lindeman had been admitted to the Medical Service of St. Luke's Hospital. They were all transfused by Dr. Lindeman and later splenectomized by Dr. Downes. Two of the cases were of the type in which there was marked cerebral symptoms and should not have been operated upon. There was a continuation of symptoms and death in both cases in from two to three weeks. The other three cases had done remarkably well, and while a cure could not be claimed it did seem that splenectomy with transfusion both before and after operation offered more in this disease than any treatment yet proposed.

Dr. Louis Hauswirth said the remissions in the disease were just as long after transfusion in pernicious anemia as they were after splenectomy. One of his cases in which the hemoglobin remained 85-90 per cent. for eleven months showed in spite of it continuous blood evidence of the disease. Splenectomy did not relieve gastric or nerve symptoms any more than did transfusion. Both were palliative only. If splenectomy did no more than transfusion, the theory of splenectomy could not stand.

Dr. Richard Weil said he wished to speak of a point of technical interest, namely, the use of sodium citrate in transfusion. This substance had for a long time been in use in the laboratory to prevent the coagulation of blood, and doubtless its availability to keep blood fluid for transfusion had occurred to others. In animal experiments, guinea pigs which had been exsanguinated from the carotid could be restored by the intravenous injection of citrated blood. In human subjects the intravenous injection of citrated blood, in amounts up to 250 c.c., had been well borne, although it had as yet been tried in only a limited number of cases. Further experience was required to test its general availability. Citrated blood could be kept for some time in the ice box without undergoing any notable change. As regarded the capacity of the red cells to take up and lose oxygen, or their resistance to toxic agents, the injection of considerable amounts of sodium citrate intravenously in human beings, such as five grams in 25 c.c. of water, had been tried in a number of cases, and had not been found to diminish the coagulability of the blood.

Dr. Ottenberg, in closing the discussion, emphasized some of the points brought out in the paper.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 22, 1914.

The Secretary, Dr. George W. Kosmak, in the Chair.

Reports of Renal and Ureteral Anomalies.—Dr. Henry Dawson Furniss presented this report.

Case I. Dr. Furniss said this was a case of single

ureter and kidney. A mass the size and shape of a slightly enlarged kidney overlay the pelvic brim. Cystoscopy showed only one ureteral orifice on the left side, the same side upon which the mass was observed. The trigonum was distorted, there being no right angle. No kidney could be discovered on the right side and the mass overlying the pelvic brim proved to be the left kidney.

Case II. This was a case of single ureter dividing and supplying the two kidneys. The patient had a large mass in the region of the left kidney, but only one ureteral opening into the bladder and that was on the right side. After injection with collargol the radiograph showed the pelvis of the right kidney filled, and about five inches from the bladder there was an offshoot toward the left kidney. The whole ureter on the left side was filled only for a few inches.

Case III. This was a case of four ureters which was discovered accidentally. Both supernumerary ureters opened one-half inch in front of the normally situated ureters and in a line between them and the urethra. Both ureters on the left side were catheterized and injected with collargol and radiographs showed that the upper pelvis corresponded to the ureter opening nearest to the urethra. This was the usual distribution found in all cases having similar anomalies.

Four Ureters.—Dr. Furniss reported thirteen cases of three ureters which had come under his observation. Of these, nine occurred on the right side and four on the left. Most of these anomalies had been discovered during cystoscopic examination and were not related to the troubles for which the patients sought relief. Only a few of these cases needed special mention. One was a case of real hematuria from the right side in which upon cystoscopy a dimpling was seen at the inner and proximal side of the ureter which could not be catheterized and from which indigo-carmine was not excreted. This kidney was removed and had a complete double pelvis. Dr. Furniss said he was unable to tell at what point the ureters fused, but thought it must have been near the bladder on account of the dimpling that resembled a ureteral orifice. In another case a double pelvis was encountered in which there was a double ureteral orifice on the right side which showed the usual distribution, that was, the ureter from the upper pole of the kidney emptied nearest the urethra. This anomaly was discovered while working on a cadaver. In another instance there was a stone in the ureter that supplied the lower pole of the kidney, and when first seen there was no elimination of indigo-carmine from that ureter. After the removal of the stone the function improved. This obstructed ureter as seen through the cystoscope appeared larger than its fellow on the same side and smaller than the one of the opposite side. This had been observed in some of the other cases also. One patient came with a history of having been constantly wet since birth. After diligent search following the administration of indigo-carmine a very minute opening was discovered just below the urethral orifice. This opening could be catheterized for a distance of one inch. Cystoscopy showed two normally situated ureters functioning normally. This supernumerary ureter was implanted into the bladder through the vagina and the patient had thus been relieved of her discomfort. In another instance the patient had had the left kidney removed on account of infection. For the same reason a nephrotomy was done on the right side; only one pelvis was opened. The kidney discharged a portion of the urine through the loin and the rest through the bladder. Before operation Dr. Furniss thought he saw two ureters on the right side, but could not be certain. In a recent case having two ureters he had been unable to pass a catheter into the ureter that was situated to the inner side of the normal one. In this instance indigo-carmine was eliminated from the two right ureters at different times. Most of the cases with two ureters on the same side could be be catheterized, but in his opinion the elimination of indigo-carmine at different times furnished sufficient evidence of two complete pelves and ureters.

Dr. Clarence G. Bandler reported five cases similar to those reported by Dr. Furniss, having two ureters on the left side and one on the right. After injection with collargol the x-ray showed the classical arrangement spoken of by Dr. Furniss, namely, the catheter introduced into the lower opening went to the upper pole of the kidney and the other orifice led to the lower pole in each case. During the past month he had seen two such cases, which was rather unusual. During the past three years he had had five such cases and two of them during the past month. Dr. Bandler showed several radiographic slides illustrating the classical arrangement above referred to. Other pictures and pyelographs of double ureters were also shown. The point of interest in this demonstration was that all of these cases showed two ureteral orifices on one side of the bladder, and all were discovered by cystoscopic examination.

Dr. D. W. Tovey reported a case of urinary incontinence similar to the one described by Dr. Furniss. The patient was a young woman who had had urinary incontinence since childhood. A cystoscopy showed two normal ureters emptying into the bladder. This patient also had a tubercuolous kidney which was removed. She was operated on by the Kelly method but the incontinence still continued. Later the supernumerary ureter was found just behind the urethra; it was turned into the bladder and the patient had no further trouble.

Dr. Leroy Broun said that in regard to the rarity of the occurrence of double ureters, Wertheim stated that he had found double ureters seven times in 500 operations for carcinoma of the uterus. In one case there were double ureters on both sides; in three on the left side, and in three on the right side.

Dr. Furniss, in closing the discussion, said that in a recent talk with Dr. Bandler he had been told that Huntington claimed to have seen only five cases of ureteral doubling in five thousand dissections. According to Huntington the most usual form was that of double pelvis and ureter, the ureters fusing before reaching the bladder. This was a condition in which there was apt to be much confusion, especially when one pelvis was infected and the other not, as it was then often a matter of chance as to which one a ureteral catheter would enter. One of his cases was of this type; in all the others there was a double ureter and double pelvis, proved in every instance by ureteral catheterization and x-ray, or by the different time of elimination of indigo-carmine.

Horse-Shoe Kidney, with Anomaly of Ureter.—Dr. J. R. Losee reported this case and presented the specimen, which was obtained from a macerated fetus having a congenital umbilical hernia and a deformity of the left forearm. The lower poles of both kidneys had fused and the bridge between them was made up of renal tissue and not of a fibrous band as was some times observed in these anomalies. The lower pole of the kidney was situated at the brim of the pelvis and opposite the bifurcation of the aorta. This position was due to the fact that fusion took place from the fifth to the seventh week of embryonic life before the kidney ascended into the abdomen. The pelves had not united and from the right side there were two ureters which ran a parallel course and entered the bladder separately. On the left side there was one ureter which had a normal course throughout.

Ovarian Cyst with Twisted Pedicle.—Dr. G. W. Bandler reported this case, which was interesting because of the onset and duration before operation. The patient, a woman about 40 years of age, a multipara, noted during the summer that her abdomen had become enlarged. In September she had an attack of abdominal pain which confined her to bed for three days. In October she had another severe attack of abdominal pain, equally severe on both sides. Her family physician suspected kidney stone. After suffering for five weeks the patient was able to be up and about. Her abdomen was hard and she suffered from obstinate constipation. When he first saw the patient Dr. Bandler said he made a diagnosis of ovarian cyst. At operation a little more than two weeks ago he found a large cyst reaching far above the umbilicus and intimately adherent to the anterior abdominal wall and to the lateral surfaces of the abdominal cavity. This tumor, greenish chocolate in color, was carefully loosened from its attachments to the anterior abdominal wall, the lateral wall of the pelvis, the great omentum, numerous coils of intestine, and particularly the sigmoid flexure. There was no point, except a certain area on its posterior surface, that was not glued to some interabdominal tissue. After extraction the tumor was seen to have originated from the left side, forming a complete twist of the pedicle, which was no thicker than a thumb. After removal considerable time was spent in applying hot abdominal pads to the numerous oozing surfaces. A large Morris drain was introduced down to the left side. The patient made an uninterrupted recovery.

A Case of Hydatid Mole with Malignant Tumor of Vulva and Vagina.—Dr. S. W. Bandler reported this case, in which, he said, fortunately for the patient but

unfortunately for the scientific interest, the tumor had proven not to be malignant. It had been his belief that hydatid mole and choric-epithelioma were evidence of epithelial proliferation resulting from lack of a protective ferment or secretion in the body. When the laboratory report on the small associated vulvar tumor stated that there was malignancy it seemed that this was an instance of the lack of a protective element. It was found, however, that the tumor was not malignant and neither was the vaginal infiltration. The patient was a woman 50 years of age, the mother of eleven children, the last born thirteen years ago. She had menstruated regularly until three months before admission to the hospital. Two weeks before admission she began to bleed and continued to do so for several days when a sudden hemorrhage occurred lasting half an hour. During the period of amenorrhea she had suffered from burning sensations in the stomach, vomiting, and failing appetite. Opinions varied as to whether the case was one of pregnancy or of myoma. The uterus was unevenly enlarged. Because the uterus was much larger than the period of amenorrhea warranted Dr. Bandler made a diagnosis of pregnancy and myoma. During the four days intervening between this diagnosis and operation the uterus increased in size fully one-third so that an unusual condition was recognized. Examination under anesthesia revealed that they were dealing with a hydatid mole. After the uterus was thoroughly emptied, during which time several hypodermics of pituitary extract were given, a small pedunculated tumor of the vulva was removed, and sent for laboratory examination. The convalescence was complicated by an involvement of the glands of the neck, first on one side and then on the other. A large infiltration of the left side of the vaginal wall was later discovered which, in view of the report on the vulvar tumor, was considered malignant in nature. A specimen of this infiltration was sent for pathological examination. This proved to be granulation tissue and a review of the vulvar tumor showed that in all probability it was not malignant. Some pus was later aspirated from the vaginal infiltration which showed the presence of *B. coli* and possibly pneumococci. The infiltration was still present and on this account hysterectomy was not being considered.

Report of Cases Showing the Value of Pituitary Extract in the First Stage of Labor.—Dr. S. W. BANDLER presented this report, consisting of a few selected cases in which he had used pituitary extract in the first stage of labor. He made the report because after the last meeting he had been taken to account for advocating or practising the use of pituitary extract in the first stage of labor with the cervix dilated to admit one finger. The cases which he reported were private ones, seen and examined regularly during the entire period of gestation. From these regular examinations and from the pelvic measurements he knew with what kind of cases he was dealing and that they were what might be called safe cases. In every instance the head during the last weeks of gestation was firmly engaged in the pelvic brim, well moulded, and in practically all instances very well through the pelvic brim. In other words, they were cases in which there was no doubt that a birth by natural channels was as absolutely safe and certain as any physician could wish. Only in such cases did he venture to use pituitary extract in the first stage of labor, and then he never gave more than one-half an ampule at any one injection. He judged of the frequency with which the injection should be repeated by the progress of events and by the duration of the pains which resulted from the injection of the pituitary extract. There was no reason why one should not make use of this drug to distinguish between true and false labor pains. Often times one found by the administration of a small dose of pituitary extract that the irregular discomfort and so-called pains of irregular character were really attempts at labor, and that if only a little stimulation of the right sort was added at the right time they would progress with a saving of much time to both the obstetrician and the patient. Dr. Bandler reported four cases illustrating these points and said that they by no means included all of those for which he had used pituitary extract in the first stage. In cases in which the membranes had ruptured before the onset of labor, at the beginning of irregular attacks of pain, the use of one-half an ampule of pituitary extract might save hours of time by introducing a regular rythmical labor at once. Dr. Bandler said that he prized pituitary extract highly in the second stage of labor in primiparæ and that it had done him wonderful service in these cases and especially in multiparæ might readily be imagined from the fact that he found its use frequently indicated in the first stage of labor.

Dr. JOHN O. POLAK said that in the discussion which he had had with Dr. Bandler after the last meeting he had maintained that Dr. Bandler's teaching in reference to the use of pituitary extract was bad and he still held the same opinion. All men were not competent to handle this drug as was Dr. Bandler. The practitioner who did not see so many cases of labor was not always competent to say whether the child's head would come through as an expert obstetrician could do. Dr. Polak said he agreed perfectly with Dr. Bandler that pituitary extract was useful when employed as he had employed it in a limited number of selected cases. He had employed it in that way himself. But it should be remembered that pituitary extract was a very potent drug and also that there was a great difference in the strength of different preparations and a difference in the susceptibility to the drug of different patients. In his experience he had seen one-half an ampule of pituitary extract throw a uterus into clonic spasms, shake a placenta loose and result very disastrously to the child. Dr. Bandler had had some good results with this drug and was very enthusiastic about it but he had not gone far enough to see the bad results that might follow its use. The drug had one field of usefulness and that was in the second stage of labor in primiparæ and multiparæ, and in multiparæ where the head was engaged and the membranes about to rupture. When it was given the obstetrician should see that chloroform, ether, and forceps were ready at hand. The reason he said this was that he had seen instances in which the fetal heart was around 140 and the head in the vagina, and after the administration of less than one-half an ampule of pituitary extract the fetal heart dropped to 60 and the child was born asphyxiated as the result of titanic uterine spasms. Another warning should be added and that was that pituitrin should never be given in the third stage of labor for the control of hemorrhage unless accompanied with ergot. The main point in determining the advisability of using pituitrin was whether the particular head in question could pass through the pelvic outlet, and if the general practitioner was going to use this drug he must avail himself of the safeguards to which he had just called attention and should use it only in suitable cases and not as a matter of convenience.

Dr. BANDLER, in closing the discussion, said that he was very glad that Dr. Polak had said that the teaching that pituitary extract should not be used indiscriminately should go out as the teaching of the Section. It certainly should not be used except with certain well-defined indications. The paper set down very distinct and sensible indications for the use of the drug. However, to say that the members of this Section ought not to exchange views because their ideas might be wrongly used outside by the general practitioner was not the proper stand to take, nor was it any reason why he should not use the drug under discussion. In the discussion on "twilight sleep" it was brought out that there were certain dangers and that the method should only be used with certain safeguards and the same thing was true in reference to pituitrin; it should only be used where there were proper safeguards as he had pointed out, but that was no reason why they should not talk about it to one another. Dr. Bandler said that he followed his primigravid cases closely and knew just what to expect when they came to term; if forceps were used, at the worst they would be low or median forceps cases. If one would go slow and give the pituitary extract in small doses it would do no harm and with the membranes unruptured it was difficult to understand how small doses could do harm. If the head was well moulded and through the brim the child would pass without danger and he would rupture the membranes when complete dilitation denoted the second stage. It was to be regretted that they did not have the pituitary extract in standard solution; the strength of the solutions differed. He never gave a full ampule but only one-half or one-third an ampule. Multiparæ were ant to have a long and tedious first stage and one might frequently give one dose of one-half an ampule of pituitrin and see what happened. Frequently after giving the first dose the labor was over within three hours. In multiparæ it was most useful as a diagnostic aid and might save the patient much pain. As he had said in the paper, pituitary extract was only indicated in the first stage of labor, when the head was

firmly engaged, well moulded, and partly through the brim. It shortened labor by one-half. In his discussion of "twilight sleep" the point he had wished to make was not that the method was unworthy of use; if pain was forgotten and shock saved he was certainly in favor of the method, but the point he wished to make was that a pituitary effect was rendered innocuous by the scopolamine and morphine. It was not a drug foreign in action, it was a secretion. It added in many cases what the organism was supplying too slowly or in an imperfect form. It stimulated the uterus to effectual muscular contractions and accomplished only what nature did of her own accord in many cases.

Extraperitoneal Lipoma Simulating Cyst of the Kidney.—Dr. JOHN O. POLAK of Brooklyn reported this case. He stated that mistakes in the diagnosis of intraabdominal conditions were so frequent in the practice of every abdominal surgeon that the man who was always right became dangerous, for each error made one more careful in his interpretations of clinical findings. The following case nicely illustrated this statement. The patient, a woman 35 years of age, was admitted to the Jewish Hospital, Brooklyn, on November 28th. Her family and personal history were negative, but since marriage she had complained of slight pain in the left iliac region toward the end of each menstruation. Her last menstrual period occurred two months prior to her admission to the hospital. Four weeks before admission she was suddenly seized with sharp pain in the left iliac region, followed by abdominal tenderness, distention, fever, and nausea. The acute symptoms continued for two weeks and then she began to bleed from the vagina. The flow lasted eight days. A tentative diagnosis of ovarian cyst with a twisted pedicle, complicated by peritonitis, was made. Operation was refused. The abdominal distension was especially marked in the lower half, and tenderness and tension were appreciable over this area, being especially marked in the left hypogastrium and the right iliac region. A firm rounded, smooth, mass was palpated in the hypogastrium, extending from the symphysis to within five cm. of the umbilicus and to the left of the median line, for a distance of 10 cm. A diagnosis of intraligamentous myoma was made. At operation an iliac lumbar tumor was found which was a large lobulated lipoma including all the perirenal structures surrounding the lower pole of the kidney. The redundant folds of thickened peritoneum were infolded and the entire area peritonealized. A small but unobtrusive appendix was also removed. The recovery was uneventful save that a definite extraperitoneal exudate could be palpated from the pelvic brim to the right kidney. The pathological report confirmed the clinical diagnosis.

Primary Sarcoma of the Ovary.—Dr. POLAK reported this case because of the rarity of this condition. The patient, a woman 19 years of age, was admitted to the hospital on November 7th. Her last menstruation had occurred on August 29th. Just after this date she observed that her abdomen seemed to be enlarging; this enlargement was rapid and progressive, at first without pain, but later with attacks of sharp pain referred to the right and left iliac regions. These attacks of pain were usually accompanied by vomiting, but there was no disturbance of pulse or temperature. A mass was noted in the right supraclavicular region, while a firm insensitive mass the size of an orange could be palpated in the upper and outer quadrant of the right breast (lympho-sarcoma). The heart was displaced upward and to the left. A large firm mass was also palpated in the central and left side of the abdomen, extending upward from the pelvis to above the umbilicus. Rectoabdominal examination showed the uterus carried upward and forward by an abdominal tumor the size of a child's head. A diagnosis of sarcoma of the ovary with ascites was made. Through a peritoneal incision several gallons of serosanguinous fluid was evacuated and a tumor of the left ovary exposed. The tumor ruptured during eventration and was seen to contain tissue of a friable brainlike structure. The right ovary, the size of a hen's egg, was also sarcomatous. Both tubes were immensely hypertrophied and edematous. To control hemorrhage a subtotal hysterectomy and a double salpingooophorectomy were done and the peritoneum drained with a Mikulicz bag. The operative recovery was prompt, but, as was to be expected, the patient lost ground and died about eight days later. The diagnosis of primary sarcoma of the ovary was confirmed by the laboratory.

Dr. S. W. BANDLER said that he had been interested in this intraligamentous myoma and retroperitoneal lipoma because they pointed to an embryonical tendency or weakness. The situation was such that with the colon in front of it percussion might have led to a diagnosis of a retroperitoneal tumor. This was a point where they were frequently confused and it seemed that the percussion note gave some information as to whether the tumor was in front or behind the colon.

Dr. FRANK R. OASTLER said that as to the diagnostic value of percussion over the colon in retroperitoneal tumors, he did not think it was of as much value as Dr. Bandler seemed to think. In such cases he had gotten no tympanitis and yet the tumors proved to be retroperitoneal. Last June he had had a case of hydronephrosis etxending over the median line and percussion gave no tympanitis over the ascending colon or cecum. Percussion was not of much value in retroperitoneal tumors.

Dr. ALFRED M. HELLMAN said that in regard to Dr. Polak's case of primary sarcoma of the ovary, the condition was very rare. In looking over the tumors of the ovary at the Frauen Klinik of the Berlin Charité of the last ten years, he had found many epithelial tumors, but only six fibroids and no sarcomas. In malignant tumors of the ovary the operation should be very radical, and the uterus should have been removed even had the hemorrhage not compelled this step.

Dr. POLAK said that this apology for removing the uterus was that there was a metastatic condition and also for the control of hemorrhage. They were in a position where they had to do one of two things and they chose the lesser evil. As to the diagnosis of intraperitoneal myoma, if one inflated the colon with air it brought out the tumor; by the use of the thermocautery bulb one could make out the tumor unless the woman was very fat.

Early Ectopic Pregnancy Associated with Double Ovarian Cysts.—Dr. GEORGE W. KOSMAK presented this report of a patient who was admitted to the Lying-In Hospital on December 1, 1914: She was twenty-two years of age, the mother of one child delivered instrumentally in 1912. Her last menstruation occurred during the last week in October. About November 20 she begun to bleed, and this continued up to the time of her admission to the hospital. Careful inquiries failed to elicit that the patient had skipped a menstrual period, neither could any history of pain be elicited. The patient was admitted to the hospital for curettage following an incomplete abortion. The uterus was found slightly enlarged and soft but the cervix was hard. The discharge of blood had been noted at this time. On careful palpation the left adnexa seemed to be more painfully felt than the right, but nothing definite could be determined from the examination. A suspicion of ectopic pregnancy was, however, present, and the patient was prepared for operation. Examination under ether revealed a distinct enlargement about the size of an orange in the left iliac region and a laparotomy was done. As soon as the peritoneal cavity was entered bright red blood was encountered and a considerable number of formed clots. A mass involved the left ovary and tube. The ovary was decidedly enlarged and the site of an irregular lacerated wound evidently due to the rupture of a thin walled cyst. The left tube was embedded in a mass of blood clots which extended on the posterior surface of the broad ligament and at approximately the middle of this mass a finger-like clot protruded from an opening which was believed at the time to be the site of the rupture. The tube was considerably thickened throughout its entire length and was removed together with the cystic ovary. Examination of the right adnexa showed a cyst of the ovary as large as a goose egg which was unavoidably ruptured during delivery. The right tube was normal. The patient made an uneventful recovery. Subsequent and more careful examination of the specimen showed that they were dealing not with a tubal rupture but with a tubal abortion. The finger-like clot previously referred to projected from the fimbricated extremity of the tube. Microscopic examination of sections through this clot showed a few chorionic villi. Sections of the ovary showed cysts of the Graafian folicles and a corputs luteum of pregnancy. The particular interest in this case lay in the absence of the classical symptoms of pregnancy. There was no disturbance of the mentsruation and aside from the slight bleeding nothing to call attention to the presence of an ectopic pregnancy. The case illustrated the necessity of careful examination of all cases of suspected uterine abortion and the advisability of doing an exploratory operation in cases

in which the uterus itself did not furnish sufficient evidence of pregnancy. The outcome in this case must be regarded as certainly better than the natural conclusion which would have resulted in the production of an hematocele with a possible pelvic abscess later on.

Dr. S. W. Bandler emphasized the fact that he had had many cases of ectopic pregnancy which did not go over the period more than one or two days and some which did not go over at all. After all there seemed to be no reason why menstruation should not take place at the right time when the ectopic was in the outer end of the tube. Hence there was often no reason for suspecting such a condition if the physician had been taught to always expect a period of excessive amenorrhea as an essential symptom of ectopic pregnancy.

Dr. Frank R. Oastler said that in a series of 69 ectopics there were about 38 which had not skipped a period and the only symptom was irregular bleeding or a longer period of flowing, sometimes seven to ten days or even two weeks. Another interesting feature of this singular case was the double ovarian cyst with the ectopic pregnancy. The etiology of ectopic pregnancy was not definitely understood. In many cases there was no disease of the tubes or ovaries so far as one could tell, no definite pathology, and in such cases sections had been made and studied but with no results. This case was one in which there was an apparent cause, but there were many in which there was no demonstrable cause.

Dr. John O. Polak said that Dr. Kosmak had mentioned the finding of fresh blood on making the inspection; it had been impressed on him that in cases in which there was a suspicion of ectopic pregnancy one should not make an examination under an anesthetic. Some men seemed always to see these cases in the tragic stage and this should not be the rule. He had written about one hundred and fifty letters to prominent obstetricians throughout the country asking the symptoms of ectopic pregnancy and about 80 of the replies had classed the chief symptom as that of metrorrhagia, and particularly if the patient had been curetted and the metrorrhagia had persisted.

Dr. Kosmak, in closing the discussion, said he was convinced that the tubal abortion in his case had occurred the day before the examination under anesthesia was made as there were a number of dark clots as well as bright ones.

Rupture of a Pregnant Uterus Bicornis Unicollis.—Dr. David W. Tovey reported this case. He stated that there was so great a variety in the manifestations of congenital defects of development in the uterus that for a long time it was thought that they were accidental and did not follow well-defined lines which govern congenital deviations from the normal in the fetal and infantile body as a whole. Anomalies of the womb depended upon an arrest of Müller's ducts, the nature of the anomaly depending upon the time at which the development of the uterus was arrested. If there was an arrest or fusion before the twelfth week a greater or lesser duplication of the womb resulted. After the twelfth week a uterus bicornis or a septate uterus resulted. If there was an arrest at a very early period there might be simply a rudimentary bundle of muscle and connective tissue fibers. The upper parts of the ducts of Müller formed the hydatids of Morgani, the middle of the Fallopian tubes, and the lower the uterus and vagina. In a uterus bicornis unicollis the junction of the two ducts was quite intimate below so there was a single cervix without dividing septum, but directly above this the two uterine halves diverged sharply from each other. In the instance reported the patient was 29 years of age and the mother of children. She was sent to Dr. Well's clinic with the diagnosis of dead fetus of about three months and a fibroid. Dr. Well's diagnosis was pregnancy of about four months in one horn of a double uterus. An attempt was made by the house surgeon to remove the fetus and placenta, but this was found impracticable and the uterus and cervix were packed with iodoform gauze to cause dilatation and perhaps expulsion of the uterine contents. The following morning the patient was in good condition and was having regular pains. The pains stopped and during the afternoon the patient went into a state of shock. She was given ether and the house surgeon again attempted to empty the uterus. With forceps a piece of omentum, the remains of the fetus, and part of the placenta were removed, and the uterus irrigated with strong iodine solution. The house surgeon said all the iodine solution returned. Dr. Tovey said that in Dr. Well's absence he was called in later and decided to open the abdomen. The abdomen was opened by a Phannenstiel incision, and a double uterus found, one cornu being enlarged by pregnancy and there was a hole the size of a silver dollar near the septum between the cornu. A supravaginal hysterectomy was done. The patient recovered after having had a stormy first twenty-four hours. Examination of the removed specimen showed a uterus bicornus unicollis, with a hole about the size of a silver dollar near the septum between the two uteri. The pregnant cornu contained a piece of placenta two by four inches. The other horn was fully developed as were also the tubes and ovaries. The single cervical canal was dilated; the supravaginal part contained the ovum and part of the membranes. Dr. Tovey said they believed that after the uterus was packed and ergot given there were uterine contractions which ruptured the uterus. The patient was in shock and the pains stopped suddenly as they always did when the uterus ruptured. Some years ago a prominent gynecologist wrote to fifty experienced gynecologists throughout the country asking them how many times they had perforated the uterus. All confessed to one or more times. The subject was brouhgt up for discussion before the New York Academy of Medicine and the consensus of opinion was that unless there was injured intestine, a large hole in the uterus, sepsis, or poisonous fluid injected into the peritoneal cavity, the best treatment was to pack the uterus and wait. Otherwise immediate laparotomy should be done. As there was no doubt but that the uterus was often punctured during curettage, Dr. Tovey said he would like to bring about a discussion of its treatment in this society. In their clinic nothing but ring forceps were used to clean out the uterus and only saline was used for irrigation unless they were sure the uterus had not been perforated. Most perforations occurred just above the internal os on the posterior wall. All that was necessary was to pack the uterus, open the posterior cul-de-sac and pack it with gauze, thus walling off the perforated area. If there was a large hole, or intestine or omentum had been brought down, the uterus should be packed with gauze and the abdomen opened. The removal of retained products of conception was much more difficult and dangerous than most abdominal operations.

Dr. William T. Moynan said that it seemed to him that the severe shock in this case might have been due to iodine entering the peritoneal cavity or touching the intestine. In cases where this was liable to happen they sewed the peritoneum to the skin to prevent touching the intestines and used saline solution.

Dr. Leroy Broun said he would not use iodine under such conditions, but Dr. Bevie had advocated the use of iodine in sterlizing the uterine cavity. He used a 50 per cent. solution of the tincture and injected it under pressure. He had found on opening the abdomen that at times the iodine solution had passed through the open ends of the tubes. At no time had he noted any ill effects from this; of course his patients were under anesthesia.

Dr. Tovey, in closing the discussion, said that he did not believe the iodine caused the shock. The danger was not from the iodine, but when the uterus was perforated there was danger of an infection being carried into the peritoneal cavity. He had put iodine all over the lower pelvis during a Wertheim operation and there had been no bad effects.

An Unusual Case of Abductor Paresis.—E. D. Davis reports the case of a healthy gardener, aged 47, who complained of loss of voice of gradual onset, and that fluids occasionally went down the wrong way, following an attack of influenza five years previously. In January, 1910, a well-marked weakness of the arytenoideus, with the typical triangular interval behind the vocal processes, and the approximation of the anterior two-thirds of the vocal cords, was seen on vocalization. There was no evidence or history of rheumatism or syphilis. Skiagraphy of the chest and examination by the direct method were negative. No fixation of the arytenoideus could be detected. Treatment by faradization valerian, etc., had no effect. An examination in June of this year showed that the paresis had progressed considerably, and that the abductor paresis was practically complete. The nervous system had been repeatedly examined, and on the last occasion by Gordon Holmes, who found no signs of organic disease. —*Proceedings of the Royal Society of Medicine.*

SENILE PARAPLEGIA.*

BY M. ALLEN STARR, M.D., LL.D., SC.D.,

NEW YORK.

PROFESSOR OF NEUROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS; MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.

AMONG the diseases of old age is one which seems to have received little attention in the text-books and in recent literature. I refer to a condition which may be designated as senile paraplegia, although this symptomatic title really includes a number of different pathological conditions. These I shall attempt to analyze, in order that the distinction between them may be evident, and that the treatment appropriate to each may be indicated.

Old age is a relative term, dependent upon the inherent vitality, power of endurance, and vascular condition of the individual, and many persons at the age of sixty-five are more feeble than others at the age of eighty-five. The term senility is, therefore, an elastic one, and is not to be limited to any particular date in one's existence. The conditions here described may, therefore, occur in anyone after the age of sixty-five, depending upon his general strength and vitality.

The clinical picture presented by these cases is quite similar in the first symptoms which we can distinguish. The individual becomes gradually more and more feeble, and notices first an increasing disability in walking, in going up stairs, or in standing for any length of time. This undue weariness goes on to an actual feebleness of movement, no longer compensated for by the use of canes or help, and finally results in a partial paralysis of movement, so that it is with difficulty that the patient moves from room to room or chair to chair, and finally becomes bedridden. In some cases the weakness is attended by a marked ataxia, the incoordination being more extreme than the actual weakness. In some cases pain is a very prominent symptom, felt either on motion only, or on standing, although it may occur spontaneously, and is particularly severe after exertion and towards night. The pain is not infrequently attended by sensations of numbness and tingling, and is always attended by coldness of the feet and legs, and an objective coldness of the surface. Occasionally, however, burning pain has been complained of, even though the surface was felt to be cold.

An atrophic condition of the muscles is quite natural in a feeble old person, but in these cases the atrophy is very often quite pronounced and is attended by a loss of the mechanical excitability of the muscles to percussion and by loss of the tendon reflexes. The limbs, as a rule, are flabby, cold, and blue, showing that the vasomotor condition is below normal, and the circulation sluggish; not infrequently edema occurs when the patient is out of bed. Occasionally a loss of control of the sphincters occurs late in the course of the case, although this form of weakness is to be carefully distinguished from that due to local disturbances in the prostate gland in men. This distinction is important, as one might wrongly conclude from the appearance of some inability to control the bladder that a spinal lesion was present.

Pain in the back, and around the loins, is a frequent accompaniment of senile paraplegia, and gives rise to much discomfort and distress, particularly at night, when it is liable to lead to insomnia. The mental state of discouragement consequent upon the gradually increasing feebleness is a point which is not to be overlooked. As a rule, we have no affection of the hands or arms, or of the back above the shoulders.

When these cases are studied simply with a view to ascertaining their pathological basis, it seems possible to distinguish between certain groups. First, those in which the primary disease lies in the muscles alone and may be likened to a muscular dystrophy or atrophy, slowly progressive in character and attended by many of the discomforts which muscular weakness entails, with relaxation of ligaments and removal of support which muscles give to joints. Along with this condition the vasomotor symptoms are quite prominent, and the paresthesia and pain, the defective circulation and edema, may all be present without any apparent lesion of the nerves.

In another group of cases it is evident that there is an active degenerative neuritis present, which is characterized by a great deal of pain of a spontaneous character, by burning and tingling, by tenderness all along the nerves and by great tenderness to pressure on the limbs and increased pain on any motion. In these cases it is not uncommon to find areas of hyperaesthesia and areas of anesthesia in the feet and legs. I have found that the anterior crural nerves appear to be more frequently affected than the sciatic, and not infrequently considerable pain is felt about the rectum and the bladder, showing that all the finer branches of the sacral plexus share in the degeneration.

Thirdly, there are cases in which it is evident that the spinal cord is the seat of the disease. The symptoms particularly indicating a spinal involvement are the appearance of an incoordination and ataxia in the early stages of the disease, and the early involvement of the sphincters. In the spinal cases the atrophy appears to be rather more rapid in its progress than in the muscular and nerve cases, and the entire progress of the disease appears to be more rapid in this type. In the later stages trophic symptoms in the skin are more frequent in this type than they are in the others, and the dif-

*Read before the Practitioners' Society, Dec. 4, 1914.

ficulty of preventing bed sores is sometimes very great, especially when the patient is very thin and has little fatty or muscular padding to protect his bony points. In this class of case, it seems as if a venous congestion of the lower portion of the spinal cord might be considered as the pathological condition present, leading possibly to an edema of the cord and an imperfect nutrition rather than a state of active myelitis. The condition in the cord of myelitis, excepting as an acute infectious disease, or as a result of injury, appears to be very rare, whereas these degenerative states, possibly to be designated as myelo-malacia, a necrosis from imperfect nutrition, may be fairly common.

I have seen several of these cases of senile paraplegia, probably of spinal origin, which have developed in individuals who have been subjects of cancer or tuberculosis, but who had no symptoms of secondary involvement of the spinal cord, and who yet suffered from marked senile paraplegia.

The prognosis in all of these cases is manifestly a rather unfavorable one, although in all of them I have seen great variations in the course of the case, and a very marked improvement, more or less temporary, under treatment. In the muscular cases there is no question that a very vigorous, stimulating diet, with meat, fatty foods, and an excess of water, with a diminution in the amount of salt in their diet, and a mild stimulation by alcohol and small doses of strychnine, will give rise to some arrest in the progress of muscular degeneration and an improvement in the symptoms. In these cases, also, warm baths of a temperature of 100°, continued for twenty minutes, with mild massage, given preferably under the water, followed by dry massage or alcohol rubs, followed by rest in bed, warmed by hot-water bottles, cause a great deal of benefit. In the cases where there is a manifest neuritis, on the contrary, baths and all manipulation of the limbs and massage have to be avoided on account of the extreme tenderness, and if local applications are made they should be soothing lotions, applied lightly on soft linen cloths, and kept warm by heating the bed. In the spinal cases hot and cold douches to the back, massage of the back and of the limbs, dry cupping to the spine, have been found of special service, and in these cases it is wise to instruct the patient to lie on the stomach, so the gravitation will aid in emptying the congested veins. It is possible in these cases that tonics containing strychnine and digitalis may be of some service.

These cases are easily separable from the spastic type of paraplegia due to lateral sclerosis, in which stiffness and rigidity, with greatly exaggerated reflexes, are marked symptoms, a condition not often seen in old age. They need not be confounded with the paraplegic condition of slow onset appearing late in Parkinson's disease; where the tremor is usually a prominent, though not a uniform, symptom, and where the gait is slow, shuffling, and stiff, with a tendency to fall.

A few illustrative cases which have recently occurred in my practice may make these conditions a little more evident:

Case I.—J. C. F., a fairly vigorous old man of eighty-two, has been suffering for the last two years from intermittent attacks of severe pain and weakness in the legs and back. I have seen him frequently during this time with Dr. Bolton Bangs, and on each occasion he has been suffering greatly from pain in the back, pain down the legs, at times in the sciatic distribution at times in the anterior crural distribution, with tenderness along the nerve and cutaneous hypersentitiveness. He complains of burning pain, alternating with a sense of great coldness of the limbs, but even when his complaint is of coldness, the surface temperature of the legs and feet is manifestly high, and they are warm to the touch. Heat, however, is the only thing that seems to give him relief from this discomfort. There has been a progressive atrophy of the muscles of the legs, and in these muscles there are at times some fibrilary twitchings and occasional cramps, which are painful. The knee-jerks are lost and the mechanical excitability of the muscles to percussion cannot be elicited. There is no anesthesia, but there is a subjective difference in the sense of touch which is somewhat blunted below the knees and in the feet, as contrasted with the thighs or arms.

The mechanism of the bladder has been markedly interfered with on account of an enlarged prostate, but there is no paralysis of the bladder or rectum, and this defective mechanism is not to be accounted for by any affection of the spinal cord. The body is extremely thin, so that the bony portions are very prominent and while in bed, unless his position is changed frequently, a marked redness appears on the surface, suggestive of a beginning bed-sore, but fortunately none have appeared on account of the care with which he has been attended.

When he is suffering from the intense pains, there is a feeling of great weakness, but there has never been any true paralysis and he has always been able to walk across the room with the aid of an attendant, and this condition is not a stationary one, for after six such attacks of considerable pain, there has been a partial recovery so that he has been able to go out in his automobile and go about, going up and down stairs with a little aid, and during the last two years at least ten months of the time have been passed in considerable comfort, but a recurrence of the pains and weakness has been frequent, without any apparent cause, unless it is probably exposure to cold.

The condition during the interval between the attacks is not, however, one of health, for there is a good deal of weakness and a degree of atrophy that is more than one commonly sees, even in an old man. Furthermore there are trophic changes which coincide with the attacks of pain, consisting of erythema and eczema of the legs, with great itching, which has required local treatment and which has subsided with the subsidence of these painful attacks. In this case, therefore, we have an example of a senile paraplegia which is manifestly due to intermittent attacks of neuritis, a neuritis which affects both the motor, sensory and trophic function of the nerves, and which is sufficiently severe to confine the patient to bed for periods of time, varying from six weeks to three months.

The condition is not to be ascribed merely to feebleness of old age, although this mistake might easily be made on a cursory examination,—because at no time in the history of the patient has there been any involvement of the arms or hands, the strength there having been normal throughout. Nor can the condition be ascribed to an arterial sclerosis, for, although this condition is present in the patient in a mild degree, yet the symptoms, it will be noticed, are confined to the lower extremities, whereas in arterial sclerosis they are present throughout the entire body.

Case II.—R. W., aged seventy-two, had been quite well until July last, when, after a rather unusual walk of three miles, he felt considerable weakness in his legs and a sense of unusual fatigue, and a few hours later considerable pain across his loins, and some shooting pain down his legs.

He rested easily that night, but the next morning on arising found that his legs were very awkward, and that he could not balance himself firmly upon them. He walked with difficulty and felt some numbness in the soles of his feet and had some difficulty in micturition.

His physician did not find any paralysis of motion or sensation, although the subjective numbness in the feet continued, but he was distinctly ataxic in his gait. It was not necessary to use a catheter, but the action of the bladder was not normal, there being a tendency to retention and difficulty in starting evacuation. The condition was not sufficient to warrant his remaining in bed, but it has remained about stationary ever since, and when I saw him in October, he was no better than he had been in July.

Examination showed a very ataxic gait, although he could walk without assistance, and without a cane. His steps were irregular in length, the feet not being

placed where he intended and there being occasionally a slipping of the foot in walking. This stagger was increased by shutting his eyes, and a very marked Romberg symptom was easily elicited. The knee-jerks were lost, and there was no ankle jerk to be obtained. There was a subjective pain felt in both feet and in the outer part of the legs below the knee, also to some extent on the inner side of the leg below the knee to touch. The sensation of pain and temperature in these areas was diminished, but not lost. Sensation of pain and temperature were markedly delayed. The muscular sense was somewhat impaired, as he could not place his foot in the same position given passively to the opposite foot, nor was he sure about the position of his toes, whether flexed or extended. There was no anesthesia of the buttocks, or around the waist. There was no girdle sensation. He had no pain in his back or limbs.

There was no local condition in the prostate to explain the difficulty in micturition, which consists chiefly in the delay in the act and the need of straining. There was no affection whatsoever of the hands. His pupils were normal and re-acted to light. There was no history of any luetic infection, and the sudden onset of the ataxia, together with the general history of the case, the absence of shooting pains or other indications of locomotor ataxia, make it possible to exclude that disease.

The diagnosis of a small thrombus in the spinal vessels affecting the lumbar enlargement of the cord, and producing a small area of myelomalacia of irregular distribution, seemed the most probable diagnosis.

The prognosis seemed unfavorable, as the condition has been stationary for the past four months.

Case III.—Mrs. F., who had been operated on for cancer of the breast in 1905, had made a good recovery without recurrence, when she began to suffer in 1912 from a gradually increasing weakness of both legs, attended by paresthesia of the feet. She has now reached the age of seventy-four, and is a fairly well-nourished but very small and delicate woman. All of her muscles are thin and rather feeble and she has never been able to take very much exercise, but in the past three years the weakness of the legs has exceeded that of the arms, and in October, 1912, this weakness had proceeded sufficiently to confine her to her bed or to make it impossible for her to walk without the assistance of two nurses.

The legs were markedly thin, so that there appeared to be very little muscular tissue left, and this is exceedingly flabby. The legs are streaked in places in a way which reminds one of the streaking of the abdomen in a multipara, showing the great atrophy of the muscles, especially about the thighs and buttocks, yet no one of her muscles is absolutely paralyzed and all of them re-act to a strong faradic current.

There is no tenderness along the nerves, but the entire limbs are tender to pressure. There is no anesthesia, although there is a sense of paresthesia, and the feet are uniformly cold and blue, showing that the circulation is impaired. There is no disturbance of the bladder or rectum, no pain in the back and nothing to indicate any cancerous affection of the nervous system.

Her condition has been progressive during the past three years, and has resisted all efforts of treatment. In this case nothing can be determined except a gradual muscular atrophy, without any neuritis or spinal affection to account for it. There is no family history of dystrophy and this woman's children and grandchildren are thoroughly healthy.

5 West Fifty-fourth Street.

FURTHER OBSERVATIONS ON THE TIC NEUROSIS (FOURTH PAPER).

By L. Pierce Clark, M.D.,

New York.

Last year I presented three papers upon the psychogenesis of tics based upon the clinical study of a definite case material.* The first case was that of a young man whose mental torticollis had its real origin in the stroking and petting caressments of the mother, which were continued by the patient through childhood and adult life in a habit movement of stroking his head. Later, when under great physical and mental stress he strove to break himself of the growing habit, mental torticollis resulted, the movements in which were found to be a sort of a "magic signal" bid for the resumption of the head-stroking which the patient had discontinued. By analysis this patient has been entirely cured and is now back again at his work as bookkeeper, doing as well as before his illness. The second case was that of a young woman with a mental torticollis caused by sexual repression; the tic movement was a physical counterpart of this repression. The conversion mechanism of the hysteric complex was employed instead of a substitution one as ordinarily obtains in the pure obsessive neurotic mechanism. The outcome in this case under analysis has not been so favorable as in Case I. The patient is freed from many of the active clonic twistings of the head and neck, but there still remains some degree of false motion when the patient is excited or intent upon some work requiring her close attention. She continues, however, to improve steadily. In the third paper a case of multiple tics with marked mental infantilism was given treatment. The outcome in this case was surprising when one bore in mind the enormous difficulties that had to be overcome. The young man has now lost all his tics, is cheerful, neat, orderly, and industrious. His mental growth has been marked and he is now trying for the first time to earn his own living and is succeeding at it. From the foregoing material and other cases not published I am impressed that all tics *per se* are of psychogenic origin and that their rational treatment should be along the lines of intensive mental analysis. The physical inciting agents which have been put forward as the alleged causes of tics produce a lowered mental tension and thus permit or allow the psychogenic mechanism to evolve the tic; it may safely be said that none of the alleged or obvious causes are the real causes of the tic. Its real motivation is *always* unconscious and flows out of the earliest instinctive demands of the individual sufferer. The acts in the tics are always infantile and partake of the infantile emotional reaction. The tics possess much of the senseless and incoordinate activities of the infantile impulsive movements. It has always been a difficult matter for writers upon tics to fit these crude and meaningless tic movements into the adult conscious life and activities of those possessing them. When we look upon these tics as psychophysical expressions of infancy which have been either lost from the domain of the will, running in automatic riot, or they have thrown off the yoke of control, under the incitement of shock or sudden stress, then their real meaning will come in a clearer light. Every tic is a psychobiologic fault in the individual's adaptation to his environment. This rule is without exception. The tic proves itself to be an inferior substitute, a neurotic adaptive symptom, for not meeting the adult purposes of life. Much of the professional and lay repugnance to observing and dealing with tiqueurs is no doubt due to our own conflicts with infantile thinking and acting with which we ourselves have more or less unsuccessfully coped. Probably the unconscious thought runs: "Now the tiqueur has become a man he should put away childish things."

*"Some Observations Upon the Etiology of Mental Torticollis"; "A Further Study Upon Mental Torticollis as a Psychoneurosis"; "Remarks Upon Mental Infantilism in the Tic Neurosis"; Medical Record, February 7 and 28 and March 28, 1914.

For years the clinician sought and found a physical basis for the tic. Apparently he was only lost in the maze of a dilemma when the tic came and went without even a shadow of a physical cause. Even more than the smile of Alice's cat, the tic both "came and went without the cat being present at all"—to paraphrase Carroll's Wonderland story. To-day an additional strain is placed upon our clinical adaption to the study of the tics. We must now search out the psychogenic mechanism in the neuroses and psychoses *though the organic fault be ever so prominent.* In mental medicine we must now search the psychogenic factors in biological life for the real motive of the profound degradation of physical functions in chronic convulsive disorders. The following case may be cited to fully illustrate the point:

An unmarried man of thirty was referred to me for study and treatment. The family was free from neuroses and psychoses except that the grandfather and father both had a decided tendency to incline the head to the left, the face being turned to the right; no real tic resulted in them, however. Our patient is the oldest in a family of three. He was born after an instrumental dry labor. He was a blue baby for several hours. He remained weak and puny throughout childhood. At about eighteen months he walked with a straddling, slovenly gait. "His knees were weak and he walked pigeon-toed." Various devices were tried to overcome the weakness of the legs, as shown in the gait. There was a marked spasticity in both legs, which was more pronounced in the left. The spasticity, the contracture in the calf muscles and the "shambling" gait were slowly overcome, and at the age of sixteen he was fairly rid of the major portion of the whole spastic syndrome. He was backward in learning to talk, which he began with difficulty at fifteen months. The speech was scanning and syllabic, and this defect still persists in part. Some of the cerebellar diplegic syndrome, which is still shown in the speech, awkwardness, and failure to properly apportion the range of smoothness of segmental movements of the extremities, the slight dysmetria and adiokinesis embraced under asynergy or incoördination of movements. The knee jerks are greatly exaggerated and a slight general spasticity is brought out in precise tests. The nature of the cerebellar injury in which the cerebrum probably also participated, as shown in the slowness and irregularity of mental development, was probably a slight grade of Batten's type.* In spite of this birth injury handicap the boy grew into a strong man whose endurance tests in long distance cycle riding is well known to the sporting world. Adolescence was uneventful; he prepared and entered a medical school and did his student work in medicine to the average of his class until the second year laboratory work required much microscopic study. He then more or less abruptly developed a "professional" torticollis. The head was inclined to the left and the face was turned upward and to the right; the brow was also wrinkled and a few short clonic movements occurred at the end of the complete rotation of the head. The muscles involved were the left platysma, sternomastoid, trapezius, and the deep rotators. The movement of the head and face in the tic was so characteristic of the purposeful one of looking through the microscope that from a casual relationship nothing seemed wanting between the cause and effect. The patient did not finish his examinations for the year and left for rest and treatment in the country.

It was thought that this patient had a mild form of cerebrocerebellar diplegia which entailed slow and delayed physical development, upon which an intense mental strain was placed by a severe test of getting a medical education, in the second year of which the arduous microscopic work brought on a professional tic of the torticollis type. Just at this point when our organic interest of cause and effect has been more or less satisfied and neurological science has little further interest, we shall make an attempt to discover the psychologic mechanism by which the tic movement really originated.

On close scrutiny we find a peculiar personality in a boy who apparently learned easily in school yet required special tutoring when he had to meet the regular admission requirements of a medical school. We find that while he had good mental powers he was slow in acquiring knowledge and in forming judgments. He was slow physically and could not sustain the time rhythm in a musical education. In adolescence he was continuously overactive in all sorts of sports but was always held back by his mother on account of his early lack of proper physical and mental development. He never had feelings of inferiority but was decidedly egotistical, with unbounded personal ambition. He was always of a stubborn and determined disposition. He was suspicious and sensitive, which traits still continue. He has always taken things too seriously. He was easily blocked by scruples and doubts in adolescence. He thought a great deal about his conscience but had difficulty in deciding things one way or the other; he had a great deal of indecision which made him easily discouraged. He was very finicky in his demands for order. He often had night terrors and continued to wet the bed until he was fourteen years of age. He often cried out in the night, saying "Take it away!" and claimed to be terrorized by animal dreams. In short, he had the underlying make-up of the obsessive neurotic.

Let us inquire into his psychosexual development. Patient was intensely mother-attached and when but a child of three or four he often said he was "never going to get married," or that he would marry his mother and then they would live by themselves to the exclusion of the father and the other children. He has always had dreams of accidents to the father. In many dreams the father lost his eyes, had his fingers chopped off, or was otherwise seriously mutilated (father castration complex). In literature, patient was most interested in Shakespeare's play of Hamlet. The ghost scene and the interview with the mother queen fascinated him.

While the father was sympathetic, he was of a practical turn of mind, and the patient always gained his sympathetic understanding from his mother. The isolation from other children during childhood which was largely brought about by his having been of a rather delicate physique, and the mother's extra solicitude in prohibiting boyish sports lest he come to harm made him even more dependent on the mother. His earliest recollections of the ideal situation with the mother was that of being in her lap and looking up in her face and having her pat his head. She never stroked it, but patted it at the back. Before puberty the mother told him about sexual matters and laid very heavy prohibitions upon him in many respects regarding his conduct with boys and girls; these limitations worried him considerably. About this time he succeeded in freeing himself from his mother's dominance and engaged very actively in athletic sports; he entered into cycle races, endurance contests, etc. His mother died when he was nineteen years old. Her death was a great shock to him and produced a very deep depression. He had many dreams of her which were most often those of health, vigor, and happiness.

A brother and sister relationship had existed

*"Congenital Cerebellar Ataxia (Cerebellar Diplegia)" F. E. Batten, *Clinical Jour.*, Vol. xxii, No. 6, London, May 27, 1903.

between the patient and his mother. People said that "he was the apple of her eye"; they often said to her, "How is your brother?"inferring that she was young enough to be taken for his sister.

Recently our patient has fallen in love with a girl whose family consists of three daughters, with all of whom the mother had been well acquainted. She had given approval of the family by saying to the patient that they were very nice girls, etc. The girl to whom he is now engaged and whom he had known for some years previous, had on more than one occasion after their closer acquaintance said that she thought our patient's mother was an ideal mother and that she liked her very much. This the patient thinks influenced him greatly in the further development of his love for the girl. Finally it may be said that she possesses much of the manners and physical make-up of the mother. In August, 1911, just before the attachment to the girl developed, his tic was at its worst. Immediately after, however, our patient began to improve rapidly.

To summarize: Patient had an intensive mother attachment; he received patting and caressing from the mother; there was a father antagonism and the mother laid great prohibitions on sexuality and boyish sports. These all kept our patient infantile. He had no love affairs whatever until late in adult life and never had anything to do with sexuality. Combined with this he had an unconscious desire to return to the mother for patting and caressing. It was found that the tic movement was the same kind that is generated by patting or tapping the head from behind. Having always been slow in coordinated movements and thoughts, the medical training required him to speed up, and in order to accomplish this he even took caffeine to keep awake. This situation steadily increased the nervous tension until the medical study was so fatiguing that a persistent, painful, "sticking" headache ensued. During the last few days at the medical school he had frequent dreams of the mother in which he revived the pleasant childhood experiences with her, the infantile pettings and caressings of the closest child and mother relations. He often stopped in the midst of hard study to indulge in day dreams and fancies of her, and pictured how pleased she would have been to know that he was fulfilling her desires in taking up a medical career, etc. As he became still more fatigued and even felt "muscle beatings and tremblings" in various parts of his body, he used to sink in his study chair and firmly close his eyes, thus striving to gain a respite from the aching fatigue by fancying that his mother patted his head or shoulder on the left side. At such times he made the tic movements in rhythm with the rhythmic fancy of her caressments. Soon after these orgies of pleasure the full tic movement came and he could not repress it by the strongest exercise of the will. In a few weeks it advanced to its climax, as related in our previous description.

The case is really similar to Case I of my first study of tics. In both men the libido remained infantile and mother attached; there was no masturbation, no heterosexual longings, and no real love affairs. Athletics helped both to repress the little sexuality that had escaped the mother's prohibition. In this latter case the mother's plan for a medical training was followed after her death, but the task was too great and the patient's unconscious libido escaped the penalizing task and went back to its infantile longings and derived its satisfaction there at a cost of a tic. The effort to continue his studies having lost its pursuit at adult adaptation, the dynamic force was also lost, and failure in the medical career resulted. The physical disorder at birth only paved the way for the final defect in adaption of an infantile libido to make successful an adult life work. Yet from the moment our patient made a love attachment to the girl who had been favored by the mother he began to improve; it was an adaption he could make and the disorder, now some eighteen months from its worst stage, is about "half cured." Our analysis has given the patient a new impetus and he feels he can now make rapid progress in knowing himself better and adjusting his life so as to build again the break in compensation of the mental torticollis.

SOME RECENT WORK IN CARDIOVASCULAR DISEASE.*

By LOUIS FAUGERES BISHOP, A.M., M.D.

NEW YORK.

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK CITY; PHYSICIAN TO THE LINCOLN HOSPITAL.

In a review of the work in cardiovascular diseases at Lincoln Hospital, one might examine the hospital records with much labor and gather a series of statistics, which might be of some interest and perhaps a little value. Or, one could recount the individual cases of remarkable interest that have been under observation, and these have been not a few, at least some of them having been permanently recorded in medical literature.

But it would seem that the matter of real interest is a consideration of how far the work in cardiovascular diseases at the Lincoln Hospital has reflected the progress of knowledge in this department of medicine, to be followed by an examination into the causes of failure, in so far as constructive criticism may be helpful in the future.

This is the first time that an attempt has been made to review cardiovascular disease as seen at the Lincoln Hospital and it has been made at the request of the chairman. During the fifteen years that I have been working there, a great deal has been accomplished by the profession toward the better understanding of cardiovascular disease. As far as lay in our power, this progress has been reflected by work at the hospital, by clinical teaching and papers read before societies and published in books and journals.

Fifteen years ago a text book on diseases of the heart was ordinarily divided into sections according to the particular valve affected. You found a section on mitral disease, a section on aortic disease and so on. As a slight concession to the general disturbances of the heart, there was a chapter on myocarditis, which was an indefinite diagnosis into which everything was thrown that did not belond in any other category. A few functional diseases were known. Angina pectoris included only the few instances where intense cardiac pain was present, accompanied by a sense of impending death. And that was about all. The great stress was laid upon the results of disease that could be seen after the patient was dead.

Fifteen years ago, there was dawning an interest

*Paper read before the Section on Practice, New York Academy of Medicine, December 15, 1914.

in cardiovascular-renal disease, in connection with so-called "high arterial tension," and the introduction of nitrites. The nitrites were much abused at that time. I remember often in the attempt to soften the pulse, we gave nitroglycerine in huge doses every half hour. Of course, these were cases of calcification of the arteries where the vasomotor system was not susceptible to the effect of nitrites.

At this time there developed a great interest in the symptomatology of cardiac disease, and in the next five or six years much attention was directed to the symptomatology and to the cardinal symptoms of heart disease—the enlargement of the liver, the character of the edema and changes in respiration.

And then there was a great deal of work on the finer points of physical diagnosis. Nearly everybody wanted to name some murmur after himself, and if he did not do that, he discovered some other physical sign to which he attached his name.

Then the blood pressure instruments commenced to come into use. About ten years ago, the men who were most interested in cardiology took up the use of the sphygmomanometer as a routine measure.

Before Fordham University Medical School was started, I had a Wednesday afternoon clinic, and we showed our cases. The physicans would come in from the neighborhood, and we talked over the theory of cardiovascular disease. Since then, the clinic has been given to the medical students.

But the greatest epoch was about six years ago, when MacKenzie published his book on the heart. A good many of us had read his work in magazine articles and had followed his co-workers, but none of us actually realized what MacKenzie had done for cardiovascular disease until he published the book, "Diseases of the Heart." That book revolutionized the whole conception of the pathologic physiology of the heart. It led us to a closer examination of the irregularities of the heart, and at one fell swoop put the name "myocarditis" in the scrap basket, where it remains to this day. As the name of a disease, myocarditis does not mean anything except in a limited number of cases and never did, and was simply a word used to cover our ignorance. If there is something the matter with the heart muscle it is usually the result of some general condition characterized by a disorder of some of its functions.

I cannot tell you when I lost my faith in cardiovascular disease as a purely local affection, but for a long time there had been a tendency among the workers in medical research to study cellular physiology rather than organic morphology. We came to realize that the physiology of the cell was the most important thing in the body, and that the physiology of the organs was more or less secondary to it, gradually gaining the idea that the changes found in organs were not diseases as such. Fibrosis of the heart and hardening of the kidneys and all the organs are not diseases, but the results of disease.

The disease itself is some disturbance of the nutritive function of the cells, of which the whole body is made up, which finally results in changes in the organs.

So we lost interest, in a measure, in what used to be called pathology. At least we called it "pathology," but it really was morphology. Morphology means the shape of things. The morphologist says, "Here are a lot of things that are round," and he proceeds to differentiate them according to shape. And that was what we used to call pathology.

Last Wednesday I went to a meeting of the New York Pathological Society, one of the oldest and most honorable societies in the City, which, ever since it began, has had among its members some of the best students in New York. Fifteen years ago the pathologists from different hospitals would bring organs and have them sectioned, bringing their microscopes to show the microscopical structures. At the meeting last Wednesday (I wish I had a program to show you), one man read a paper on "The Transmission Bundle of the Heart," another man read a paper on "Anaphylaxis," and still another a paper on the chemistry of the bile. Just two of the men brought pathological specimens. All the rest of the work was what might be called biochemistry, the chemistry of the cell—the fundamental changes that have to do with pathological physiology. So even the pathologists themselves (at least that group of men that constitute the Pathological Society) are interested in the life of the cell. In that way they are really studying the fundamental underlying diseases which result in changes in structure.

At the Lincoln Hospital last Thursday I lectured about a man with arteriosclerosis. This man had been in hospitals for a year, and had been treated according to the old traditions of the profession. He was regarded as suffering from morphological changes of mysterious origin. He was supposed to be suffering from hardening of the arteries, hardening of the kidneys and of the muscle of the heart. These things being permanent and that being considered his disease, nobody thought there was anything to be done for the man. So he dragged on for a whole year because the knowledge of morphology so affected the psychology of his doctors that they did not believe in curing a person with his disease.

Now if they had believed that he was suffering from a disturbance of metabolism, with the resulting changes in the arteries, and that this hardening (so long as it existed and could not be helped) was not worth bothering about, his outlook would not be so hopeless. The man was really suffering from cellular irritation. He showed the typical appearance of arteriosclerosis: He had the shininess of the conjunctiva of the eye, the pain in the chest on exertion; and passed a large quantity of urine. He carried a high blood pressure. He had been given a general diet, and took no exercise.

The natural history of this man in the light of what I believe to be the true philosophy of arteriosclerosis was this:—

Through some event in his history, which we were unable to elicit because he was not very communicative (or perhaps he did not know), but which, from the experience of a large number of other cases, I would put down either to some severe infectious disease, some attack of food poisoning or some great nervous shock, there was an alteration in his metabolism whereby his cells were no longer able to deal satisfactorily with the material which should have nourished them.

The cells are nourished by proteins. The proteins, (nitrogenous or albuminous food) pass into the body and but a very small portion of them remain in the body. That small portion, however, is infinitely necessary to the nourishment of the cell.

As long as the relation of the cells to proteins is normal, people go on, and as far as these things are concerned, they are well. The disease is started by an infectious disease (typhoid fever is followed in a great number of cases by arteriosclerosis), a

severe influenza, a gallstone condition (where a person is suffering from gallstones and is very badly jaundiced and reduced), an attack of appendicitis, or a period of life when there is tremendous worry.

One of these periods is the time when the disease starts. What takes place is that the cells become sensitized to food proteins, and from that time instead of being nourished the cells are irritated by the proteins and gradually destroyed. As long as the intake of the particular protein continues the disease advances, and the person cannot be well.

I saw to-day two men with very advanced arteriosclerosis. One of them came to me a year and a half ago suffering from a very high blood pressure, 270 mm. Hg., shortness of breath, swollen feet, and constant recurring attacks of severe cardiac pain. He considered himself (and all his medical attendants considered him) in great danger. He was very, very sick.

He was subjected to a phlebotomy of forty ounces of blood, he was put to bed for a week, and given castor oil every other day for three doses. I took out of his diet all eggs, fish, meat and stock soups, and told him to walk out of doors every day as much as he was able.

He has had his ups and downs, but at the end of eighteen months he presents the picture of good health, he is able to attend to his work, and as far as I can see is as well as he was six months ago. It took him about a year to get a readjustment of his organs. His blood pressure now is 190 mm. Hg., but he walks a great many miles out of doors every day, and is devoting himself to keeping himself alive.

Of course, when a man has a blood pressure of 270, angina, dropsy, and albumin and casts in his urine, he is a pretty badly damaged man, and all you can do is to teach him so to live that the progress of his disease may be checked.

This man seems to be sensitive to the proteins of eggs, fish, and meat. Any time he goes back to eggs he is sick. Of course, meat is out of the question—anyone would have told him to give up meat with his bad kidneys, but eggs and fish were just as bad in his case.

The other man came to me about the same time, with a history of having been perfectly well until one day he could not see out of one of his eyes. He went to an oculist who told him he had arteriosclerosis. I propounded to him the above theory of his disease: That he was suffering from a disturbance of metabolism, and that he should treat not his organs but his cells. I put him on a diet but he was not satisfied. He said he wanted to see other doctors, so he went to Europe and saw the best authorities in France, Germany, and England. He came back with the written opinions of the most famous doctors he could find in those countries. He canvassed all the different opinions of the various doctors as to the nature of his disease. It was very interesting because he said, "No one agrees with you entirely, but when I come to take the underlying thought in the minds of all these different doctors I think they all have the same idea, but you have put it more definitely than most of them. They all think it is due to a disturbance of metabolism, but they don't all carry it to the logical conclusion in considering it a cellular disease and not an organic disease."

We subjected this man also to the same treatment. We had to bleed him (I have forgotten how many times) when it seemed something more was going to happen to him. He has been very faithful to his diet, has taken castor oil at regular intervals, has kept out of doors, and is still alive enjoying himself.

At the Lincoln Hospital I teach the idea that these are cellular diseases and not purely organic diseases, and that we should try to cure them. Because you cannot improve the lesion does not mean that you cannot cure the disease.

There is no reason why many a hospital patient should not be well, but there is a psychology with which you have to deal. The hospital patient often has no ambition. He does not want to work for his health—and he would rather sit down and take medicine. The men referred to above were different—they wanted to get well. They missed the food poisoning and craved meat, but they were strong enough to avoid it. You—any of you—could give up meat and not miss it, but if you were poisoned by it you would miss it and crave it. It requires a good deal of strength of mind for a person with advanced arteriosclerosis to give up offending proteins.

The only people who do well with these advanced cardiovascular diseases are people with sufficient intelligence to appreciate the importance of the regimen. That is the reason the treatment of cardiovascular disease in the hospital is so hard because the patients do not want to get well and nobody expects them to get well.

So to sum up, I would say that in the fifteen years that we have studied cardiovascular disease in the hospital I have seen the transition from the study of the changes that are the result of the disease to the study of the disease itself, in other words, the disturbance of the physiology of the cell.

When I think of a meeting of the Pathological Society fifteen years ago and the meeting I attended last Wednesday the change is quite vivid. Now we are coming down to the fundamental causes of disease. You will probably all live to see the day when we will speak more definitely of the diseases of the cells and know more about them. Of course, now much is experimental. You put a little horse serum into a guinea-pig, and in forty-eight hours more serum will kill it. In other words, you sensitize the cells of the animal to protein and that protein becomes a violent poison. When a man becomes sensitized to meat, that man is poisoned by meat. Later on his cells may be destroyed and he develops cardiovascular disease.

The application of these advances in our knowledge of the pathology of the cell to these chronic degenerative diseases is to me one of the most interesting things I have run across in medicine.

I have the care of so many people who are suffering from all stages of arteriosclerosis who are well and have become free from all their symptoms by the discovery and removal of their protein poison that I cannot help but believe the theory.

There is another thing that has come out recently: The sensitiveness of cells may be local as well as general. There may be a localized anaphylaxis. That is very curious. You inject a lot of animals with serum, and some of them, instead of getting a general anaphylaxis, develop an inflammation of the cells of the eye, the kidney, or some other group of cells. This is possibly sometimes the origin of that mysterious condition known as albuminuric retinitis. In all these studies it must be remembered that bacteria act as proteins and that a focus of infection may act in the same manner as the continuous administration of a protein.

The McKenzie polygraph has been in constant use in my wards for some years, and at one time we made elaborate studies of sphygmomanometers. I present with this paper about a thousand ink polygraph tracings which are a graphic record of the nature and progress of the heart beat of a large number of cases, both in hospital and private practice. A technical discussion of these would be interesting, but I have chosen rather to recount our progress, or, at least, our change of opinion, as to the philosophy of cardiovascular disease, because that is what influences treatment which has too often been lost sight of in the intense study of diagnosis.

54 West Fifty-fifth Street.

THE INTERVERTEBRAL FORAMINA IN MAN.*

By HAROLD SWANBERG,

CHICAGO.

(From the Anatomical Laboratory, Chicago College of Medicine and Surgery.)

WITHIN the past quarter of a century various schools of practice have directed a great amount of attention from a therapeutic standpoint to the intervertebral foramina. Pathological changes occurring in or around these areas are responsible for nearly all the ills man is heir to, according to the claims of many. The entire philosophy of at least one school of practice is based upon the theory that practically all pathological conditions are due to pressure upon the nervous structures in the intervertebral foramina. A careful review of the literature reveals the surprising fact that there has not been published any study concerning the minute structure of these parts. We are told how the intervertebral foramina are formed, that they convey nerves, arteries, and veins, but as to the detailed structure of these apertures, the size of the nervous structures as compared to the foramina, etc., we are told nothing. In view of the above facts, a brief description of one of these foramina should be of more than passing interest.

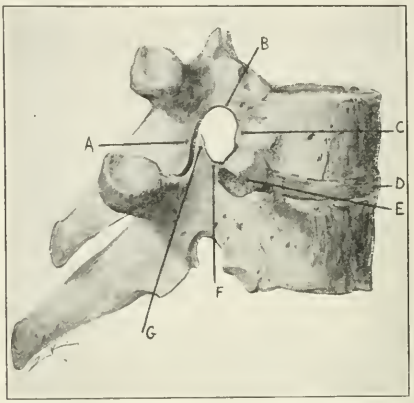

FIG. 1.—A right lateral view of the seventh and eighth thoracic vertebræ, with the intervertebral fibrocartilage connecting them, and the head of the right eighth rib. A—Inferior articular process of seventh thoracic. B—Root of vertebral arch (pedicle) of seventh thoracic. C—Body of seventh thoracic. D—Intervertebral fibrocartilage. E—Head of eighth rib. F—Root of vertebral arch (pedicle) of eighth thoracic. G—Superior articular process of eighth thoracic.

Specimen.—The necessary specimen was secured from a five-months-old male infant. At this age the intervertebral foramina are of such size as to

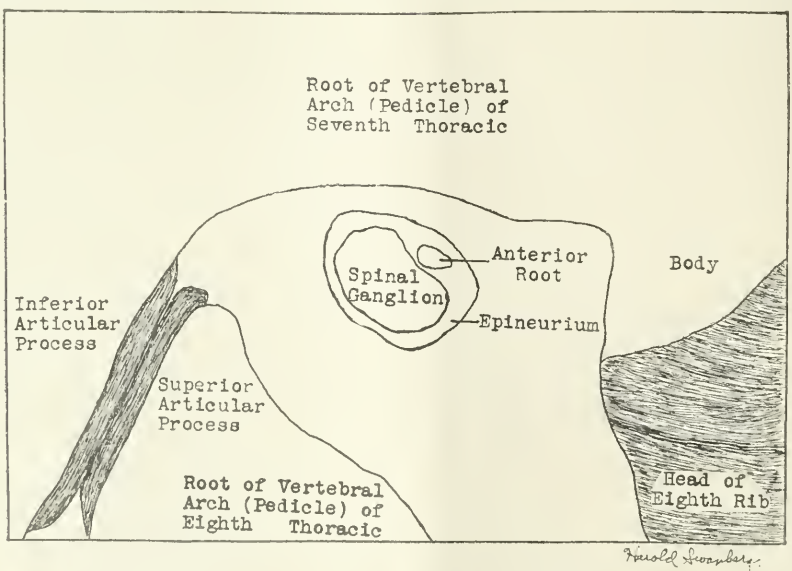

FIG. 2.—A right lateral view of the right seventh thoracic intervertebral foramen and its adjacent bony boundaries with the position and size of the roots of the right seventh thoracic spinal nerve. (Outline drawing from Fig. 3.)

*My book, "The Intervertebral Foramen," published in January of last year, reviewed in the MEDICAL RECORD, May 9, 1914, page 865, contains the first histological description of an intervertebral foramen and its adjacent parts to appear in the literature. The foramen described in this work was from a cat. In the MEDICAL RECORD, Nov. 14, 1914, page 852, I reported that I had made microscopic studies of several intervertebral foramina and adjacent parts in man, and had found them to be similar to the one described in the original work. The object of this article is to describe one of the above-mentioned intervertebral foramina of man, and to briefly summarize my findings concerning the most important facts of the anatomy and histology of this part.

be very suitable for microscopical examination. The infant had been normal in every respect until eight days prior to its death. At this time it developed a bronchopneumonia. The right seventh thoracic intervertebral foramen was selected for study. The right half of the seventh and eighth thoracic vertebræ, with the vertebral extremities (head and neck) of the right seventh and eighth ribs attached was used as the specimen. The specimen was put through the usual histological technique, the bone being decalcified with dilute nitric acid. It was then placed on a block with the part where the spinal cord and the bodies and laminæ of the vertebræ had been cut longitudinally resting on the block, and mounted in this position. The sections were cut approximately in the sagittal plane, from without inward, and labeled accordingly. Such sections cut the nervous structures almost transversely as they emerged from the intervertebral foramen, thereby giving a complete view of the foramen. Section 1, therefore, shows structures considerably lateral to the intervertebral foramen, while Section 49, the last one, is in the vertebral (spinal) canal. Forty-nine sections in all were prepared, there being an average of about 180 microns between each. Photomicrographs of only three of these sections (Sections 38, 30 and 23) are given in this description.

Description of Figures.—Figs. 1 and 2 are drawings which are shown in order that the reader may better understand the photomicrographs which follow. Figs. 3, 4 and 5, the remaining ones, are retouched photomicrographs of the right seventh thoracic intervertebral foramen and the area lateral to it. They are all equally enlarged. In the retouching no attempt was made to conceal the results of faulty technique, thus every part is shown practically identical with the original slides. Each figure corresponds to a section and the figures are enumerated from within outward; that is, reversing the order in which they were cut. Fig. 3, the first photomicrograph, is a section cut through the intervertebral foramen; the remaining two figures (4 and 5) are sections cut lateral to the intervertebral foramen.

Description of Fig. 1.—This figure shows a right lateral view of the seventh and eighth thoracic vertebræ, with the intervertebral fibrocartilage connecting them, and the head of the right eighth rib. The seventh thoracic intervertebral foramen is located between the seventh and eighth thoracic vertebræ. Bony boundaries of intervertebral foramen.—Anteriorly: Body of seventh thoracic vertebra above; head of eighth rib (below body). The external lateral part of the seventh thoracic intervertebral fibrocartilage also forms an anterior boundary, but this is not shown here, it being medial to the head of the rib. Posteriorly: Inferior articular process of seventh thoracic above; superior articular process of eighth thoracic below. Superior: Root of vertebral arch (pedicle) of seventh thoracic. Inferior: Root of vertebral arch (pedicle) of eighth thoracic.

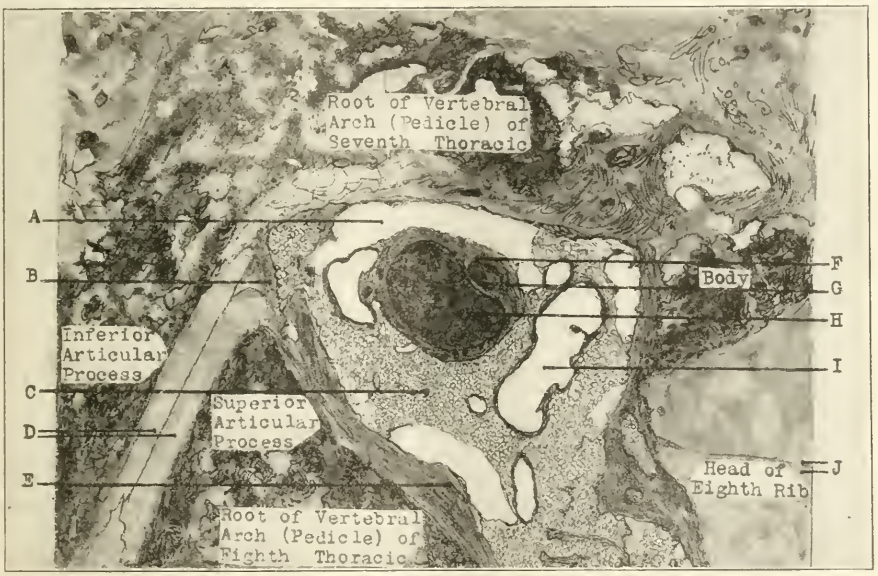

FIG. 3. (Section 38)—A right lateral view of the right seventh thoracic intervertebral foramen, and its adjacent bony boundaries. A—Vacant space. B—Capsular ligament. C—Fat tissue. D—Articular cartilages. E—Fibrous tissue. F—Epineurium. G—Anterior root of spinal nerve. H—Posterior root of spinal nerve (spinal ganglion). I—Blood vessel. J—Articular cartilages.

Description of Fig. 2.—This plate is an outline drawing of Fig. 3, and shows the right seventh thoracic intervertebral foramen and its adjacent bony boundaries, with the size and position of the roots of the right seventh thoracic spinal nerve. The intervertebral foramen has the same bony boundaries, and is shown in the same position as in Figure 1. The entire boundaries are not present. They are deficient inferiorly, owing to their projection at different levels. The darkened areas represent the hyaline articular cartilage. Articular cartilage on bony boundaries.—Hyaline articular cartilage is found on the following parts: (1)

Inferior articular process of seventh thoracic; (2) superior articular process of eighth thoracic; (3) body of seventh thoracic; (4) head of eighth rib. The articular cartilage is found on the articular processes where they articulate, and on the body of the vertebra and head of rib where they articulate. The size and position of the roots of the seventh thoracic spinal nerve are shown in the upper central part of the intervertebral foramen. The small anterior one is the anterior root, the large posterior one is the spinal ganglion of the posterior root. The roots are surrounded by epineurium. They occupy about one-fifth of the total area of the intervertebral foramen, and are free from any bony contact. The other structures in the foramen, fat cells, fibrous tissue, and blood vessels, are shown in the photomicrographs which follow.

Description of Fig. 3 (Section 38).—This figure is the most medial one shown in this series, and presents a right lateral view of the right seventh thoracic intervertebral foramen and its adjacent lymph spaces or channels convey lymph from the spinal cord. In all probability the lymph passes through the intervertebral foramina in these spaces.

(1) Nervous structures.—Anterior and posterior roots (spinal ganglion on posterior root). The position of the roots has been discussed in connection with Fig. 2. Each root is separately surrounded by the epineurium, which also serves at the same time to connect them. They are free from any bony contact and are embedded in fat tissue. (2) Blood vessels.—Numerous blood vessels of various sizes are embedded in the fat. (3) Fat tissue.—Fat forms the most abundant constituent of the foramen. (4) Fibrous tissue.—Fibrous tissue forms the epineurium of the nervous structures, periosteum of the bone, part of the walls of the blood vessels, and is a constituent of the fat tissue. The above occurs in all the sections. It is well to remember that all fat tissue has more or less fibrous tissue in connection with it. The capsular ligament, connecting the articular processes, is composed of fibrous tissue.

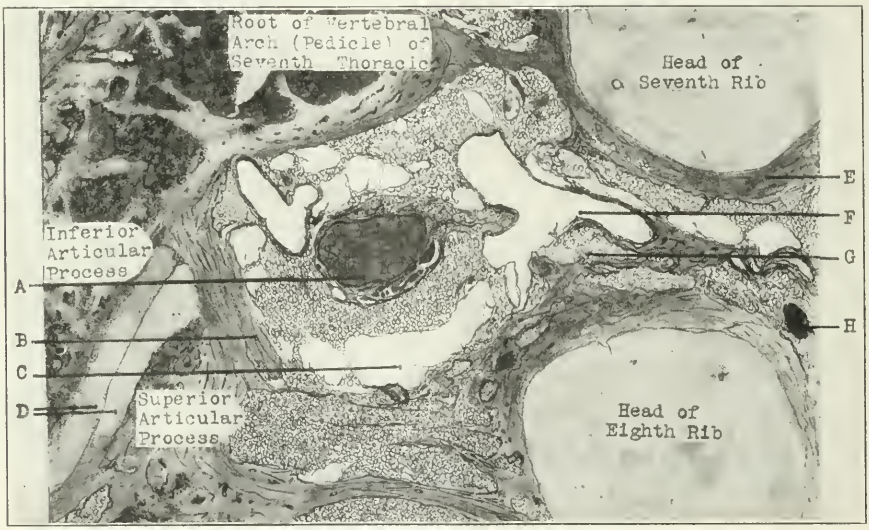

Fig. 4. (Section 30)—A right lateral view immediately lateral to the right seventh thoracic intervertebral foramen. A—Spinal nerve. B—Capsular ligament. C—Vacant space. D—Articular cartilages. E—Fibrous tissue. F—Blood vessel. G—Fat cells. H—Lymph node.

bony boundaries. It is shown in the same position as Figs. 1 and 2. The same general directions that were given in connection with the above figures will apply to this one. Bony boundaries of intervertebral foramen.—The bony boundaries are similar to Figs. 1 and 2. The reason for the deficiency of the bony boundary inferiorly was given in connection with Fig. 2. Articular cartilage on bony boundaries. —The articular cartilages are similar to Fig. 2. Contents of intervertebral foramen.—The contents are (1) nervous structures; (2) blood vessels; (3) fat tissue; (4) fibrous tissue, and (5) vacant spaces.

No lymphatic vessels can be recognized in these photomicrographs. Their presence can only be proved by special injection methods. So far as our present knowledge is concerned, the entire nervous system is alike in a lack of lymph vessels. Like practically all parts of the body, however, it has a lymph supply. All nerve cells are more or less surrounded by pericellular lymph spaces Perivascular (5) Vacant spaces.—Spaces occur at various situations in all the sections in which all tissue is absent. They are, no doubt, due to faulty technique, and probably represent areas where fat cells have been washed out in the process of preparing the specimen.

Description of Fig. 4 (Section 30).—This is immediately lateral to the right seventh thoracic intervertebral foramen. Bony relations lateral to intervertebral foramen.—Anteriorly: Head of seventh rib above; head of eighth rib below. Posteriorly: Inferior articular process of seventh thoracic above; superior articular process of eighth thoracic below. Superiorly: Root of vertebral arch (pedicle) of seventh thoracic. In this and in the following photomicrograph the position of the bony parts are named according to their relations to the cerebrospinal nervous structures. The head of the seventh rib has replaced the body of the seventh thoracic and the root of the vertebral arch (pedicle) of the eighth

thoracic has disappeared. Articular cartilages.—Articular cartilage is found on the following parts: (1) Inferior articular process of seventh thoracic; (2) superior articular process of eighth thoracic.

Tissues Lateral to Intervertebral Foramen.—The tissues present are similar to those in the former figure, except for the addition of lymphoid tissue. (1) Nervous structures.—The Spinal nerve. The anterior and posterior roots seen in the former figure have united and the spinal nerve is formed. It is surrounded by fat tissue and blood vessels. (2) Blood vessels.—Numerous blood vessels of various sizes are embedded in fat tissue, as in the former figure. (3) Fat tissue.—Fat is the most abundant tissue present. (4) Fibrous tissue.—The fibrous tissue is arranged similar to the former figure, except that it appears slightly increased in amount. (5) Lymphoid tissue.—A lymph node is present anterior to the head of the eighth rib.

Description of Fig. 5 (Section 23).—This is lateral to the right seventh thoracic intervertebral foramen, lateral to Fig. 4. Bony relations lateral to

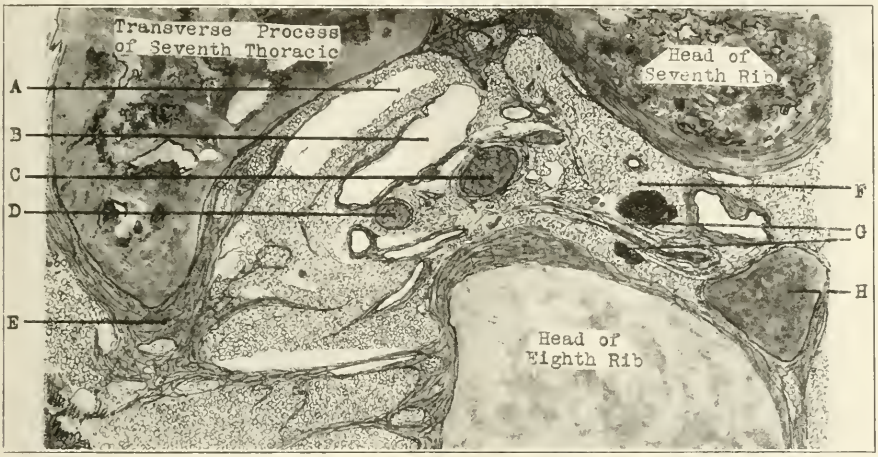

Fig. 5 (Section 23).—A right lateral view lateral to the right seventh thoracic intervertebral foramen, lateral to Fig. 4. A—Vacant space. B—Blood vessel. C—Anterior ramus (primary division) of spinal nerve. D—Posterior ramus (primary division) of spinal nerve. E—Fibrous tissue. F—Fat tissue. G—Lymph nodes. H—Sympathetic ganglion of sympathetic trunk.

intervertebral foramen.—Anteriorly: Head of seventh rib above; head of eighth rib below. Posteriorly: Transverse process of seventh thoracic. Superiorly: Transverse process of seventh thoracic. The transverse process of the seventh thoracic has replaced the root of the vertebral arch (pedicle), and the inferior articular process of this vertebra. The superior articular process of the eighth thoracic has disappeared. Articular cartilages.—None of the bones present articulate with one another, hence no articular cartilages are present.

Tissues Lateral to Intervertebral Foramen.—The tissues present are similar to the former figure. (1) Nervous structures.—1. Anterior and posterior rami (primary divisions) of the spinal nerve. 2. Sympathetic ganglion of the sympathetic trunk. The spinal nerve seen in the former figure has bifurcated into an anterior and posterior ramus. As is usual, the anterior ramus is much the larger in size. The rami are surrounded by fatty-fibrous tissue. Resting on the anterior surface of the head of the eighth rib, a sympathetic ganglion is present. Like all nerves, it is surrounded by epineurium. It also is embedded in fatty-fibrous tissue. (2) Blood vessels.—The blood vessels are arranged similar to the former figures and are embedded in fatty-fibrous tissue. (3) Fat tissue.—Fat remains the most abundant tissue. There is considerable loosely arranged fibrous tissue in connection with it. (4) Fibrous tissue.—The fibrous tissue is increased in amount. (5) Lymphoid tissue.—Two lymph nodes are present between the heads of the ribs.

Summary.—Intervertebral Foramen.—The most abundant constituent of the intervertebral foramen is fat tissue. The roots of the spinal nerve, including the spinal ganglion, which are situated here, are embedded in fat tissue. They occupy about one-fifth of the total area of the foramen. The blood vessels, which are several in number and of various sizes, are embedded in fat tissue. There is a small amount of fibrous tissue present.

Lateral to Intervertebral Foramen.—The most abundant constituent is fat tissue. It is, however, infiltrated with a more or less loosely arranged fibrous tissue, making a fatty-fibrous tissue. The spinal nerve, the rami (primary divisions) of the spinal nerve, and the sympathetic ganglion are present. They are all more or less embedded in fatty-fibrous tissue. The blood vessels, which are several in number, and of various sizes, as in the intervertebral foramen, are embedded in fatty-fibrous tissue. Several lymph nodes are present.

Conclusions.—Having spent considerable time, covering a period of over three years, studying various intervertebral foramina and their adjacent parts, microscopically and macroscopically, both in animal and man, I can briefly summarize my findings as follows:

The intervertebral foramina have a definite structure. Each foramen has the following contents: (1) Nervous structures; (2) blood vessels, *i.e.* arteries and veins; (3) fat tissue; (4) fibrous tissue, and (5) lymphatics. The nervous structures present are one of the following: (*a*) Spinal nerve; (*b*) roots of the spinal nerve, or (*c*) the rami (primary divisions) of the spinal nerve. The nervous structures are usually free from any bony contact and are embedded in fat tissue. They are small

in size as compared to the intervertebral foramen through which they pass. The greatest size I have seen was where the nervous structures occupied about one-third of the total area of the intervertebral foramen; the smallest size was where they occupied only about one-tenth. The size of the nervous structures in proportion to the intervertebral foramen is not the same throughout the vertebral column, but nature has in every instance provided an abundance of room for the passage of all the structures through this aperture.

Even in cases of severe ankylosis (in which the intervertebral disks and articular cartilages on the articular processes have entirely disappeared), or marked spinal curvature, where the intervertebral foramina are greatly reduced in size, there still remains sufficient room for the nervous structures to pass free from bony pressure. The nerves can be subject to bony pressure only in such cases as actual fracture, dislocation, tumor growth, or callous formation following a fracture. These, we know, are not of common occurrence.

The most abundant constituent of the intervertebral foramina is fat tissue. As has been mentioned above, the nervous structures are embedded in this fat. Fat, in the living subject, is in a semi-fluid condition. Thus we see that the nervous structures are embedded in a semi-fluid substance, one of nature's most efficient protective agencies. This seems such an admirable arrangement that it renders injury to the nerves almost impossible in this situation. Even should the intervertebral foramina be somewhat altered in size or position, there still remains sufficient room for the nervous structures and the fat surrounding them is still in a semi-fluid condition. Since nerves are composed of such a highly specialized tissue, and therefore are so vital, nature seems to use every possible precaution to protect them from bony pressure. This is the reason, no doubt, that the intervertebral foramina, in both animal and man, are so much larger than the nerves themselves.

I take this opportunity to acknowledge my indebtedness to my friend and preceptor, Harris E. Santee, A.M., Ph.D., M.D., Professor of Neural Anatomy, Chicago College of Medicine and Surgery, for reviewing this work.

INTESTINAL PARESIS:

ITS TREATMENT BY MEANS OF PITUITARY EXTRACT.

By ELMER H. KING, A.B., M.D.,

ALLSTON, MASS.

Definition.—Perverted function of the intestine, prominently characterized by loss of tone of the intestinal musculature, of variable extent, and by extreme gaseous distention of the paralytic gut, following actual obstruction, circulatory failure, or toxemia; wherein there is defect of drainage per anum but maintenance of the excretory function of the liver and of the intestinal mucosa; wherein the content of the intestinal lumen becomes extremely toxic by reason of defective drainage and consequent putrefaction; wherein the oral rather than the aboral end of the alimentary tract is utilized inadequately as the excretory vent; wherein absorption of virulently toxic material from the intestinal lumen, and the prevalence of a paralytic intraintestinal gas pressure, tend to perpetuate the stasis, and, if the condition be not ameliorated, to kill.

Etiology.—Intestinal parèsis arises under diverse sets of circumstances. The postoperative type engages our attention perhaps most commonly. A frequent experience, too, is the encountering of extreme paralysis of the bowel as the result of actual organic obstruction. There is, further, a small group of cases presenting actual functional obstruction; a segmental spasm of the small intestine for about an inch of its extent, possibly due to a reflex across the cord, or probably (1) to trauma of intrinsic plexuses. There is a large group of cases arising as the result of infectious toxemia; the tympanitic abdomen of typhoid fever, and the extreme distention occurring in the graver cases of pneumonia, are examples. Intestinal paresis is maintained as result of metabolic toxemia; extreme instances occur in nephritic toxemia having incidence with a failing heart muscle, or with postoperative vasomotor paresis, or with both; absorption of toxic, putrefactive excrement of the intestinal mucosa and the liver from the intestinal lumen, after stasis is once established, serves to perpetuate the bowel paralysis.

Predisposing are obesity, enteroptosis, adhesions which cripple the movements of the gut, cardiorenal disease, and infectious toxemia, with reference particularly to cases of postoperative incidence.

A preliminary, tentative, classification is offered: Intestinal Paresis: I. Arising as result of circulatory failure: (a) Vasomotor paresis, (1) postoperative (shock), and (2) following injury (shock). (b) myocardial insufficiency.[2] (c) Hemorrhage (extravascular). (d) Embolism and (or) thrombosis of mesenteric arteries.[2] II. Arising as the result of actual obstruction: (a) Organic. (b) Functional. (Dynamic ileus).[3] III. Arising as the result of infectious toxemia. IV. Maintained as the result of metabolic toxemia: (a) Nephritic toxemia. (b) Intestinal toxemia.

The cases are not always of pure type. Very frequently indeed they are not; the same case may have postoperative incidence, and may present, moreover, infectious toxemia, or metabolic toxemia and myocardial insufficiency. Nor is the classification comprehensive; isolated, rare instances occur of different etiology, as, for instance, a recently observed extreme case of lead palsy of the bowel. Osler[2] describes instances occurring in hemiplegia and following paracentesis abdominis.

Pathology.—The distended coils of intestine in intestinal paresis are familiar to all. Whether of functional or of organic origin, the end result would seem to be the same, if the condition be not ameliorated. The grave functional paresis requires as much and as prompt concern as the strangulated hernia or the volvulus; not a secondary operation, as some advise, but attention to the essential etiology and the injection of pituitary extract into a vein. The paretic bowel will usually not empty itself if an artificial anus be established. A vent is not lacking; the tone of the intestinal musculature is impaired or in abeyance.

The mechanism of the distention would seem to be clear: loss of tone of the intestinal muscle, and gas production by the action of putrefactive bacteria upon the intestinal content. The integrity of the bowel is liable to be compromised by the injurious pressure and by the infectious toxic content. Disintegrative changes occur, proceeding at times to gangrene or infection. Hemorrhage into the bowel occurs late and is probably related to the late black vomit and stools.

Earnest attention needs be accorded to the excretory functions of the intestinal mucosa and of the liver. That which we call fecal vomiting is not food residue; it is the excrement of the intestinal mucosa and of the liver, profoundly altered by intestinal putrefactive bacteria. Absorbed, it is virulently toxic, and tends to maintain intestinal paresis and to kill. Hence the need of early establishing intestinal drainage.

Symptomatology.—Detailed description of symptoms is quite unnecessary. In the grave case the distended tympanitic abdomen; the pain; the racing heart; the foul, putrefactive, copious vomiting; the hiccough; the anxious facies; the usual intolerance of the stomach for cathartics; the futility commonly attending the employment of enemata, and the abeyance or impairment of the passage of flatus and of liquid per anum are quite familiar. But there are varying grades of severity. The character of the vomitus furnishes a fairly reliable index of the gravity of a given case. In cases of lesser gravity, vomiting may be absent. Early vomiting is bilious; it may be black from an altered biliary excretion following ether anesthesia; in the graver cases it tends to become more and more offensive; later, if the patient live long enough, it may become black. The heart is prone to falter, often becoming intermittent. The hiccough is of decided interest by reason of an associated heart sign. In some instances, if the stethoscope be placed at the heart's apex, it may be observed that the hiccough is synchronous with the beginning of an extraordinarily powerful vagal arrest of the heart in diastole, which may persist throughout several heart cycles. In other instances the hiccough is double, in which case two synchronous, inhibitory impulses flow to the heart. The complex probably betokens trouble of the vagal nucleus.

Diagnosis.—It is quite essential in a given case to recognize the causation. The uncomplicated postoperative case is differentiated from the case complicated by infectious toxemia by the temperature, by the history, and by the pathology found present at operation. The case complicated by nephritic toxemia is recognized by a knowledge of renal and (or) cardiac insufficiency. Actual organic obstruction of the intestines, consequent upon operation, should be strongly suspected if, in the absence of extraordinarily grave shock, infectious or nephritic toxemia, myocardial insufficiency, or grave extravascular hemorrhage, pituitary extract, intravenously given, fail to empty the intestine, awaiting a reasonable length of time, employing the while appropriate treatment, for the return of possibly abeyant neural functions. The paretic bowel of the later stage of actual organic obstruction should be recognized. Cases of a type designated as possibly due to actual functional obstruction differ from the usual postoperative type in the character of the pain which occurs earlier, and is of agonizing, colicky type, associated with extreme spasm of the abdominal muscles, as contrasted with the steady distention pain of the usual case, which occurs later and is associated with a non-spastic distended abdomen; they differ also in the pulse rate, which is lower, 80 or thereabouts, as contrasted with the usual case in which the pulse rate is about 120. Both types resemble each other when loss of tone and distention occur late in the spastic type. From actual organic obstruction actual functional obstructional can be differentiated possibly by the outcome of treatment.

Complications.—Acute dilatation of the stomach occurs in postoperative cases and in infectious diseases, as typhoid fever and pneumonia. In intestinal paresis the stomach is pressed into service as the excretory channel for the excrement of the liver and of the intestinal mucosa and for the putrefactive products of this, notably gas. The mechanism of the distention would seem to be precisely the same as that for intestinal dilatation; loss of tone of the muscle and distention by gas derived, in this instance, from putrefying intestinal excrement. Treatment guided by these considerations will be casual rather than empirical. The prophylaxis is the treatment of intestinal paresis and of associated conditions. Pituitary extract given into a vein will commonly empty the stomach (produce vomiting) if this contain intestinal extrement, as well as empty the intestine. Gastric lavage may be employed after the administration of pituitary extract.

Acute dilatation of the heart occurs in cases of intestinal paresis. In some instances the sequence would seem to have been intestinal paresis and dilatation of the stomach, with acute dilatation of the heart closing the scene. The prophylaxis is treatment of intestinal paresis and of the associated shock, or of the possibly associated renal or infectious toxemia, not forgetting the faltering heart. The mode of death in intestinal paresis is commonly by circulatory failure; the majority gradually weaken; a few die suddenly from acute dilatation of the heart; a few suddenly from drowning following aspiration of their own intestinal excrement. Instances of infectious and metabolic toxemia complicating postoperative intestinal paresis are given in the appended illustrative cases.

Prognosis.—There is a certain definite mortality in untreated cases of intestinal paresis of the uncomplicated, postoperative type. In treated cases extreme concomitant shock probably absolutely governs the prognosis, although we have been fortunate enough not to meet such an instance. In complicated cases the prognosis may be absolutely conditioned by the complication. Infections, particularly grave postoperative peritonitides, are examples. The sequence, grave, operative, extravascular hemorrhage, postoperative vasomotor paresis, renal insufficiency, and postoperative intestinal paresis, with myocardial insufficiency following to perpetuate the renal insufficiency and intestinal stasis, furnishes an extremely grave prognosis. The prognosis varies with or without treatment; if both shock and intestinal paresis remain untreated, our mortality will be higher than if we direct measures against both; it varies, too, with or without treatment of the complications. The prognosis is worse in the obese, the enteroptotic, and the victims of adhesions which cripple the movements of the intestine.

Prophylaxis.—In the prevention of postoperative intestinal paresis the protection of the central nervous system against afferent impulses from the field of operation would seem to be of value. The foregoing proposition would probably include inflicting minimal trauma to tissues and to structures, probably also consistent speed in operating. Careful hemostasis is probably also helpful. In bad risks, choosing that type of operation which promises least spilling of the patient's blood would seem clearly the part of wisdom. In the after care, in cases in which the operation has been of sufficient gravity to warrant the assumption of presence of severe shock, early elevation of the foot of the bed, and the giving of

salt solution by rectum, unless strongly contraindicated, are in a large measure prophylactic. When the heart flags, as it so frequently does in shock, the incidence of intestinal paresis in heart disease might well be remembered. In chronic nephritics, careful preparatory treatment of circulation and of the kidneys is probably valuable. In infections the need of care for intestinal drainage is so obvious as to require no comment.

Treatment.—Action of pituitary extract: The current teaching is that pituitary extract directly stimulates smooth muscle tissue. Probably the extract does not add a single dyne of energy to the body, acting much like a catabolic enzyme, accelerating the velocity of energy production by smooth muscle. Its action upon the intestine is dependent upon some degree of integrity of the functions of smooth muscle, of the vagi, of the sympathetic, and of the intrinsic plexuses. When the neural functions are abeyant pituitary extract is useless; we have to await their return, employing the while appropriate treatment.

Justification for calling upon the smooth muscle, in a time of dire need, for a greater output of energy lies in this: in all probability the muscle function is not nearly as defective as are the neural functions. While objection to this procedure might be urged, as it is against any stimulation, that we are whipping up a tired horse, nevertheless the horse is good for it, the goal is soon won. A period of freedom from extreme gaseous distention and from pain, permitting sleep, follows; the stomach becomes tolerant of food, and energy stores can be repleted. At any rate, in by far the large majority of cases of uncomplicated, postoperative intestinal paresis, the intravenous administration of pituitary extract is promptly curative. The intensity of the action of pituitary extract is directly proportional to the speed with which the extract enters the circulation. That is, the stimulation of smooth muscle, by 1 c.c. of pituitary extract, thrown *en bloc* into the circulation, is tremendous; while if three or four minutes be consumed in intermingling the same quantity with the flowing blood in a vein, the stimulation will be decidedly more moderate. By-effects of pituitary extract are rise of blood pressure, dyspnea, air hunger, and the production of pallor. Vomiting may be expected, and welcomed, if the stomach contain intestinal excrement. The dyspnea and air hunger are rather distressing. Their intensity is directly proportional to the speed with which the extract enters the circulation; it varies, too, with the degree of pre-existing embarrassment of the circulation; they can be largely obviated by cautious and slow injection. In any event they are exceedingly transitory and negligible when contrasted with the lasting benefit secured in the majority of cases.

Technique.—A Record syringe of 2 c.c. capacity, glass barrel, and the 20-gauge needle are suitable. Sterilization of the skin, and of the syringe and needle, can be satisfactory obtained with a 2 per cent. solution of phenol in 60 per cent. alcohol. Filling the syringe with the solution, holding it with needle attached vertically, the needle upward, then emptying the syringe and allowing the solution to flow downward along the needle, have given unimpeachable sterilization. A vein near the elbow is usually available and suitable except in fat persons, in whom a vein on the back of the hand may be more available. Choosing the median cephalic vein, thus avoiding proximity to the brachial artery, is preferable. The sterilized needle and syringe are then filled with 1 c.c. of pituitary extract, and air is carefully excluded. While an assistant makes manual compression of the limb above to distend the selected vein, the needle is thrust upward in the long axis of the vein, making downward traction upon the skin at the same time with the unengaged hand. The slipping of the needle into the vein is usually easily appreciated. To make sure, the piston is withdrawn slightly; a spurt of blood into the barrel of the syringe demonstrates certainly that the needle has entered the vein. The injection is now begun, releasing compression above, and neglecting the blood which has entered the syringe, the rumbling of peristalsis is heard usually with the injection of the first few minims; soon flatus and liquid pass. If the bowel seem more refractory than usual, the speed of the injection can be increased. The patients usually wish the window open and to be fanned. The site of puncture need not be dressed. Bleeding is inconsequential. A high saline enema given just before the injection is helpful. It is essential to have the bed-pan under the patient before the injection.

ILLUSTRATIVE CASES.

Case I.—Postoperative intestinal paresis: M. G. H.,[1] white, female, aged 54; hysterectomy for fibroids January 17, 1914. Forty hours after operation the abdomen was distended, tympanitic, and tense; the heart racing; the pain and distress extreme; morphine ¼ grain had no appreciable effect; the stomach was intolerant of everything; vomitus was not yet extremely offensive; enemata had proved useless. One c.c. of pituitary extract intravenously given produced prompt, thorough, and copious evacuation of gas and of liquid per anum. The abdomen, which had been barrel-like and tense, became flat and soft. Thereafter the pulse improved, the patient fell into a refreshing sleep, and convalescence was uninterrupted by further bowel trouble.

During hospital interneships extending over the past two years, pituitary extract, intravenously given, has been employed in just this type of cases routinely and promptly upon the appearance of the syndrome, with none but the happiest results. No case of this type so treated has succumbed. Some there have been which at first have been refractory to pituitary extract alone; but these have yielded to the extract a few hours later, after adopting shock treatment. During a like period several cases on parallel services not so treated, or treated with pituitary extract intramuscularly given or not receiving the benefit of conjoined shock treatment, have succumbed.

Case II.—Postoperative intestinal paresis: M. G. H., white, female, aged 28; cesarean section at term for maternal dystocia March 14, 1914. Seventy-two hours later the full syndrome of intestinal paresis was present. Six enemata, castor oil, calomel, and eserine had been given. Sixteen hours before the bowel had proved refractory to pituitary extract intravenously given. The foot of the bed was elevated, and salt solution by rectum started. Five hours later one c.c. of pituitary extract intravenously given effected copious evacuation of liquid and of gas per anum. Thereafter there was no further bowel trouble.

In instances of grave shock in which the bowel is at first refractory to pituitary extract and in which a contraindication exists against raising the foot of the bed, or in which we come for the first time upon a case of great urgency, the intravenous administration of normal saline may be considered. Generous quantities, up to three pints, may be employed. Effort to move the bowel by means of pituitary extract, intravenously given, may be made

toward the completion of the intravenous administration of saline, while the blood pressure is still held up by this maneuver.

Case III.—Postoperative intestinal paresis complicated by infectious toxemia: M. G. H., white, female, aged 23; unilateral renal tuberculosis, two years' duration, secondary infection twelve weeks' duration. Nephrectomy July 14, 1914. Thirty-six hours later full syndrome of intestinal paresis present; pulse 140; enemata ineffective. It seemed imperative that something be done for the patient. Very cautiously, consuming five minutes, one c.c. of pituitary extract was given into a vein. With the injection of the first few minims, gas began to pass per anum, and continued to pass for the next five minutes. The nurse later reported a large liquid result as well. Convalescence was uninterrupted by further bowel trouble. This result was nearly ideal. The whole action of the extract, so far as subjective symptoms were concerned, was confined to the gut. The patient experienced no discomfort, except slight nausea.

The effect of infectious toxemia, complicating postoperative intestinal paresis, is to make the bowel more refractory to treatment, and to bring about recurrence of symptoms, after the bowel has been emptied thoroughly one or more times.

Case IV.—Postoperative intestinal paresis complicated by nephritic toxemia: M. G. H., white, female, aged 41; panhysterectomy for fibroids January 7, 1914. Thirty-two hours later full syndrome of intestinal paresis present, although several enemata had been given. Pituitary extract into a vein evacuated enormous quantities of gas per anum; two bed-pans were required for the liquid result. The later development of almost complete suppression of urine led to the belief that renal insufficiency had been a complication. Recovery.

The extreme reduction in the size of the abdomen in this case, and in Cases I, V, VI, and IX, as well as the liquid and gas results, make the contention that the extract empties the small as well as the large intestine more than probable.

In medical practice intestinal paresis occurs in cases of renal insufficiency, usually when the heart muscle fails. In surgical practice in chronic nephritics the renal insufficiency is further augmented with the incidence of the passive congestion of postoperative vosomator paresis. Intestinal paresis is so frequent as to be almost constant. Frequently the heart muscle fails as well. These instances furnish the gravest anxiety of which we are aware. The mortality is distressingly high. Probably the prognosis can be bettered by securing early and maintaining intestinal drainage, upon which the chronic nephritic is so dependent. Whatever is done to break the diabolically vicious circle must be done early. Pituitary extract into a vein will succeed in some instances if employed sufficiently early. Sodium bicarbonate solution into the rectum may be of service. All indications should be met.

In instances of conjoint intestinal paresis, and renal and myocardial insufficiency, if the bowel prove refractory at first to pituitary extract, the intravenous administration of normal saline to which 1 per cent. of sodium bicarbonate has been added, up to three-pint volume, may be employed. Effort to move the bowel by means of pituitary extract, intravenously given, may be made toward the completion of the intravenous administration of the sodium chloride-sodium bicarbonate solution, while the blood pressure is still held up by this maneuver. In instances, by far the more numerous, in which the putrefactive vomiting is sustained and copious, requiring compensatory supply of fluid to the patient, where the renal insufficiency is for solids, rather than for water, this practice is occasionally helpful. In other instances, in which the vomiting is not so copious, and the renal insufficiency is also for water, with possibly hydrothorax ascites, and anasarca, the practice may not be employed.

Case V.—Intestinal paresis following injury: M. G. H., white, male, aged 48; admitted August 7, 1913. Accidentally sustained contusions to left arm and hip, probably broken ribs as well. August 11, there had been no passage of flatus, nor of solid, nor of liquid, except returned enemata. The abdomen was barrel-like, tense. Pain extreme. Stomach intolerant. Vomitus offensive. Pituitary extract into a vein produced delivery of enormous quantities of gas. Two bed-pans were required for the liquid result. The abdomen became flat and flaccid. No further bowel trouble.

Case VI.—Intestinal paresis following extravascular hemorrhage: M. G. H., white, female, aged 33; curretted March 19, 1914, for hydatiform mole. Admitted May 9, 1914, for extreme uterine hemorrhage which had occurred the day before. Twenty-four hours after entrance abdomen markedly distended, bowel non-responsive to enemata, stomach intolerant. Pituitary extract into a vein promptly evacuated the bowel.

Case VII.—Intestinal paresis following actual organic obstruction: M. G. H., white, female, aged 33; panhysterectomy for chorioepithelioma May 15, 1914. Secondary operation May 21, 1914, for postoperative actual organic obstruction. A loop of the jejunoileum was found adherent to operation wound in abdominal wall and kinked. After the separation of adhesions, gut was returned without anastamosis. Extreme distention of the small intestine above obstruction. While the patient was still anesthetized, pituitary extract was given intravenously for shock. Copious evacuation of gas and liquid per anum followed at once.

Case VIII.—Intestinal paresis following actual functional obstruction: Maine Eye and Ear Infirmary. R. M., patient of Dr. W. E. Tobie. Appendectomy April 23, 1913. A few hours after operation patient experienced intense, agonizing, intestinal colic. Morphine ¼ grain relieved for four hours, when pain of the same character returned. Pituitary extract was given intramuscularly, but proved useless. Morphine was accordingly given, and repeated at four-hour intervals until the morning of the twenty-fifth, when the patient was found writhing in agony from his intestinal spasm. Distention was beginning, and the stomach intolerant. Pituitary extract was given intravenously; prompt evacuation of bowel followed, with permanent relief.

Certainty can by no means be maintained that actual obstruction existed in this case, yet the instance is typical of a small group of cases which seem to correspond, clinically, with the pathology found present by others.

Case IX.—Intestinal paresis following infectious toxemia: M. G. H., white, female, aged 45; admitted August 8, 1913, ten days' postabortum, criminally induced. Temperature, 103.2; pulse, 130. Smears from bloody uterine discharge showed streptococci in abundance. The full syndrome of intestinal paresis was present. Enemata proved useless. Accordingly pituitary extract was given into a vein the following morning with prompt result. Forty-eight hours later the condition returned. Pituitary extract was again successful. Thereafter enemata and catharsis proved efficient.

Contraindications.—In pneumonia the added load upon the heart of an increased blood pressure, and the constriction of the coronary arteries imposed by the use of pituitary extract, increases the distress of the patient. Yet the intestinal drainage can be secured when all else fails with pituitary extract carefully given and later held by vigorous catharsis and enemata.

Pituitary extract should be very carefully given when the heart rate is unusually high, 140 or more, when there is marked intermittency of the heart, or in the presence of cardiac decompensation. In angina pectoris, on account of the vasoconstriction produced by pituitary extract, its use is probably

absolutely contraindicated. In subacute peritonitis, as for example the puerperal peritonitides and in postoperative intestinal paresis occurring in chronic peritonitis, as for instance tuberculous peritonitis, pituitary extract is extremely useful. It would seem that we ought not to let a patient die from intestinal paresis, even in the presence of subacute or chronic peritonitis. In the acute cases, with grave intraabdominal lesions tying up the intestine, the extract is usually useless. Each case however is a kingdom unto itself and must be decided upon its own merits.

Conclusions.—I. Pituitary extract intravenously given will empty the intestines, both large and small, per anum, oftentimes the stomach as well, if this contains intestinal and liver excrement, promptly and thoroughly, in by far the large majority of uncomplicated cases of postoperative intestinal paresis.

II. Conjoined with treatment directed toward the essential causation in any given case of intestinal paresis, proving refractory at first to the use of pituitary extract alone, it will retrieve many lives otherwise forlorn.

III. In uncomplicated postoperative cases, its action is promptly curative, and far more efficient than morphine, with reference to permanency of effect, in relieving pain due to intestinal distention or to intestinal spasm. But in a few such cases the bowel will yield to pituitary extract only after reaction from grave concomitant shock.

IV. In any given case of intestinal paresis it affords an additional means of emptying the bowel, peculiarly applicable, transcending in efficiency any we have heretofore possessed.

V. It is possibly curative of functional, actual, obstruction.

In actual organic obstruction, after a vent is established or the continuity of the bowel is assured, it may be effective in emptying the paralytic section of the gut.

THE STREPTOCOCCUS PERIL.

By HENRY F. LANGHORST, M.D.

ELMHURST, ILL.

It is just of recent date that we have begun to see the protean rôle the streptococcus plays in human pathology. We have long associated the streptococcus with erysipelas, scarlatina, and septic conditions, but it is only of late that its intimate connection with rheumatism, chorea, gastric ulcer, nephritis, septic sore throat, and other diseases has been determined. The omnipresence of this organism, its ready convertibility and the havoc wrought by its attack, prompt me to start an active campaign against it.

Hamilton,[1] in an attempt to determine whether scarlet fever patients disseminated streptococci into the surrounding air or not, placed sterile Petri dishes filled with blood-agar before patients at a distance of 12 to 24 centimeters. The patients were asked to cough twice. Out of 50 cases examined 34 were found to expel streptococci by coughing, crying or breathing. In a similar test made on 50 normal adults 42 were found to expel streptococci. That scarlet fever is caused by a streptococcus has not been proven. Its intimate relation with this disease is however an accepted fact. Baginsky and Sommerfeld[2] found streptococci in the blood of the heart and internal organs in all of 82 fatal cases of scarlet fever. Hektoen[3] states "that the predominant feature of the bacteriology of the throat in scarlet fever is the constant presence of a large number of *Streptococcus pyogenes;* that the overwhelming majority of the so-called complications and of the deaths in scarlet fever are due to the invasion of the tissues and the blood by the microbe; and that in scarlet fever, even when mild, the organism gives evidence of systemic reaction to the streptococcus by variations in the streptococco opsonic index and probably also by the formation of streptococco agglutinins. There is therefore no escape from the conclusion that the *Streptococcus pyogenes* or some form thereof plays a most significant part in the scarlatinal process." Tunicliffe[4] has shown that the opsonic index for the streptococcus falls and rises as the disease advances or declines. Liverato[5] and Schleissner[6] both found complement-deviating substances in the serum of scarlet fever patients, using the streptococcus as antigen. The streptococcus has many specific tissue affinities; it may cause an inflammation of the skin, otitis, adenitis, angina, glossitis or nephritis. In fact it will cause any of the symptoms individually that are found in scarlet fever collectively.

An interesting phase of the streptococcus study is the mutability of this organism. Rosenau has worked out this idea and has transmuted a streptococcus into a pneumococcus. It is a well-known fact that certain strains of streptococci assume different cultural and morphological characteristics under certain conditions and environment. Rosenau[7] classifies the streptococci as follows, their virulence increasing in the order named: Hemolytic streptococcus, *Streptococcus rheumaticus, Streptococcus viridans,* pneumococcus and the *Streptococcus mucosis.* The hemolytic variety has an affinity for joint structures, while the viridans has an affinity for heart valves. By a shake culture on ascites dextrose agar, Rosenau[8] was able to isolate 3 strains of streptococci from the exudate of joints in acute rheumatic fever. The cultural and morphological characteristics of each strain are different, also the affinities of each strain have specific tendencies. When the rheumatic strains under cultivation revert to the hemolytic type they lose their affinity for the endocardium and pericardium, but acquire greater affinity for joint structure. Rosenau[9] has also found (*J. A. M. A.*, November 29, 1913) that at one stage of the virulence of the streptococcus the organism shows an affinity for the mucous membrane of the stomach, duodenum, and gall-bladder. He states: "The experiments on mutation show that when these and other streptococci are grown in symbiosis with other bacteria and under a low oxygen pressure, they may acquire new features, and that sometimes they undergo marked changes on passage through animals. . . . The importance of focal infections as a point of entrance of bacteria in general is quite well recognized, but the idea that the focus serves in addition as a place where bacteria can acquire new properties is not generally recognized and needs to be emphasized."

Writers on tropical diseases have frequently mentioned the fact that scarlet fever and rheumatism are practically never seen in the tropics. In an editorial in the *Journal of the American Medical Association*, April 25, 1903, the editor under the caption "Cosmopolitan Diseases in the Tropics" writes as follows: "The concluding chapter of Scheube's translated work on 'Disease of Warm Climates,' is devoted to medical geography or what the author calls 'cosmopolitan diseases.' It gives a compendium of the facts, so far as known to the author, of the distribution of certain general diseases, and this has been made the subject of an interesting editorial commentary in the *Indian Medical Gazette* of March, 1903. . . . One of the curious facts pointed out by both Schaube and the editor is the absolute absence of scarlet fever in the tropics. While it may be imported into such regions, it never spreads, and it would be interesting to know what special cause in the temperature or otherwise there may be for this peculiarity. Erysipelas which Schaube considers rare is not at all unknown in India, and pneumonia which is unevenly distributed, lacking in some regions, is almost as serious a disorder in Indian territories as it is in Europe and America. At the present day it has come to be more dreaded in some Indian jails and public institutions than even dysentery used to be. Another disease which seems to be lacking in tropical countries is acute rheumatic fever, not chronic rheumatism, and while it occurs it is by far less frequent among the natives than is the case in other climates. . . . If scarlet fever can not exist in warm climates there ought to be some fact to account for it that might very probably be of utility in its management where it does occur, and similarly with other disorders."

In an analysis of 100 cases of arthritis in laborers on the Panama Canal, Baetz[10] writes: "Some of the most noted authorities in tropical medicine declare that acute rheumatism and scarlatina are both practically non-existent among natives in the tropics. No one will deny that scarlatina occurs in Panama in imported cases only, but question would probably be raised as to the absence of acute articular rheumatism." His results show that out of 100 cases of arthritis, 63 were syphilitic, 28 were gonorrheal, 2 were dysenteric, 1 was tuberculous and 6 were undetermined. He further mentions that acute articular rheumatism was not encountered, nor was acute or chronic endocarditis present in the 100 cases. Overlander,[11] speaking of medical practice in the Canal Zone, says: "Measles and chicken-pox thrive well and do not differ in any essential features from the same diseases here. Scarlet fever is much less common and epidemics are short-lived. It has been stated that scarlet fever is not a tropical disease and certainly the statement is well borne out on the Isthmus." Otis,[12] in his article on diseases of Porto Rico, says "Eruptive fevers, except possibly scarlet fever, are found in Porto Rico, but are usually of a mild character." In a travel letter, Caldwell,[13] writing from China, says: "As in Japan, I found here also that true croupous pneumonia is a very rare disease. They have a ward connected with this hospital for the isolation of scarlet fever and diphtheria cases. But these diseases are so rare here that the beds in this ward are nearly always empty."

In answer to a letter, sent to the Surgeon General's office in Washington, inquiring about the statistics of scarlet fever in Japan, a report of the number of deaths from this disease was sent. From 1904 to 1910 the number of deaths were, respectively, 18, 36, 70, 126, and 339. The climate of Japan is not entirely tropical, and might correspond to that of our southern States. It is not unusual to have snow fall in Japan. This fact would mean that other influences, besides climatic ones, acted as repressive factors. We will now attempt to show what we believe to be the chief factor in the prevalence of streptococcal infections.

Rosenau[14] made an attempt to secure sterile milk from healthy cows by means of milk tubes. In spite of elaborate asepsis, he succeeded only in 5 out of 12 attempts. The milk in three of the failures was found to contain streptococci that were pathogenic for guinea pigs. He made tests with the sterile milk he obtained, inoculating it with strains of streptococci derived from both human and bovine sources. He found if the milk was kept at a low temperature, conforming with the natural conditions of the dairy industry, thereby delaying or preventing the growth of the germ, that the streptococcus was altered and its virulence increased. His tests prove that no raw milk is absolutely safe. For many years epidemics of sore throat have been identified with the milk supply of the affected community, the earliest reports coming from England. Swithbank and Newman[15] say: "We think it safe to assume that a year never goes by in which there are not outbreaks of sore throat or tonsilitis due to cream or milk." In 1897 an epidemic of sore throat was attributed to the milk supply in London. At this time staphylococci and streptococci were found in the milk. In 1908 there occurred in Christiana an epidemic which was also traced to the milk supply, streptococci being found in the milk. Darling[16] and Winslow[17] each reported the epidemic of septic sore throat, occurring in Boston in 1911. Over 1,000 cases were reported, and 48 deaths were attributed to the infected milk. Streptococci and pneumococci were the predominating organisms found by cultures from the throat and milk. In this epidemic it was not possible to obtain a record of any cases of tonsilitis in the dairy employes, the assumption being that the infection was primarily from the cows. In 1912 an epidemic occurred in Baltimore and Chicago. Davis[18] reports the bacteriological finding in the Chicago epidemic. He found a streptococcus that had a capsule and somewhat resembled the pneumococcus. Capps[19] (*J. A. M. A.*, June 15, 1912) found in the Chicago epidemic an unusual prevalence of mastitis in the cows of the dairies that were distributing the infected milk. Davis found pus and streptococci in the milk taken directly from cows with diseased udders. In an editorial in the *Journal of the American Medical Association*, March 14, 1914, the editor says: "There has been a tendency in the investigation of a number of epidemics to conclude that the cause of the infection in septic sore throat is the streptococcus which is discharged from the inflamed udder of the dairy cow into the milk, through which it is transferred to the throats of the milk consumers. The evidence for the foregoing theory of infection has hitherto been circumstantial rather than positive and direct. The outbreak of epidemic sore throat at Cortland and Homer, in the State of New York, during April of last year gave an opportunity to demonstrate the correctness of the commonly held view. North, White and Avery[20], in discussing an epidemic of septic sore throat in Cortland and Homer, N. Y., state that "the incidence of

the cases in the outbreak soon cast suspicion on the milk supply from one dairy. Over 70 per cent. of the cases in each community occurred among the patrons of a dairyman who was the only dealer selling milk in both places and who furnished less than 7 per cent. of the total milk supply. Adjacent towns had no cases, and further they received no milk from the suspected dairy. As the result of an inspection of the cattle belonging to this dairy, two cows which showed physical signs of udder inflammation were isolated from the main herd and the use of their milk was forbidden. For the first time in the history of the investigation of individual cows for the existence of udder inflammation we are told a centrifugal milk clarifier was used. By means of this apparatus the milk of all animals in the herd involved was examined and the sediment easily secured. The quantitative results in the case of the two suspected animals alone furnished sufficient evidence, by contrast with the milk sediment of the rest of the herd, to point conclusively to their udders as affected; and the microscopic examinations showing streptococci, bacilli, and phagocyting white corpuscles, discharged by the inflamed organ into the milk, completed the proof."

The symptoms of septic sore throat in brief are: chills, high fever, diffuse redness of throat with excessive secretion of mucus, enlarged lymph nodes, and the crypts of the tonsils filled with exudate; very often there is a membrane that cannot be distinguished from the diphtheritic one except by bacteriological methods. The complications are manifold, consisting of suppurative adenitis, otitis, arthritis, glossitis, nephritis, pneumonia, bronchitis, myocarditis, pericarditis, pleurisy, endocarditis, peritonitis, scarlet fever and scarlatinal eruptions. From the foregoing evidence it is safe to conclude that raw cow's milk is a decided menace to the public. Milk and cream are mediums for disseminating the streptococcus among millions of people. It isnot to be marveled at that the streptococcus is all prevalent in any community where the dairy industry flourishes. Until we have stringent laws governing the milk industry, sterilization or properly supervised pasteurization of milk should be universally enforced. The streptococci that are harbored in the throat may at any time assume pathogenic properties.

Being impressed with the close relation the streptococcus bears to scarlet fever, erysipelas, rheumatism and pneumonia, also with the work of Rosenau, in which he shows the many affinities and the mutability of the streptococcus, it was thought a good plan to make a geographical study of streptococcal infections. The hope is also expressed that this study may pave the way toward a better etiological understanding of scarlatina.

In order to explain the lack of streptococcal infections in the tropics, one must consider whether the chances for disseminating the germ there are as facile as in countries where these infections are common. An inquiry addressed to the Department of Agriculture at Washington asking about the dairy industry in tropical countries brought the response that as far as they were able to tell no dairy industry of any importance existed in the tropics. Dairying is only conducted as an adjunct to the raising of livestock. It is almost impossible to get milk in Japan. There are a few small dairies there that supply the foreign residents with milk, cream and butter. This statement comes from a member of the household of a former ambassador to Japan. Overlander, in his article on Canal Zone practice, quotes: "Of children's diseases, intestinal disturbances are common. Diseases of nutrition are more rare than one would suppose. Milk is scarcely to be had even at 40 cents (gold, 80 cents silver) per quart." It is thus shown that one of the main causative factors in the dissemination of streptococci is missing in the tropical countries. This fact suggests important prophylactic procedures. It is as important to eliminate the streptococcus from our dairy products as to eliminate the typhoid bacillus from our drinking water. We absolutely refuse to drink water that is contaminated, but are not at all squeamish about taking a little pus, manure, and virulent bacterial life in our milk. The streptococcus scourge in all of its phases is important enough to demand drastic sanitary regulations.

From the available knowledge on this subject our conclusions are as follows: The streptococcus is present in the majority of human throats (in this country). It has been proven to be the causative factor in acute rheumatism, erysipelas, and epidemics of septic sore throat. It leaves a trail of damaged hearts, kidneys, ears, joints, and other serious defects in its wake. It is so closely identified with scarlet fever that by eliminating the streptococcus we would take from scarlatina its chief instrument of destruction. It is not at all impossible to believe that the streptococcus, in some form, is the causative agent. Streptococcal infections, such as rheumatism, erysipelas and scarlet fever, are not established diseases in the tropical countries. Streptococci are widely disseminated by products of the dairy. The dairy industry in the tropics has not been developed. The pneumococcus, representing one stage in the mutation of the streptococcus, is a peril that is gaining in power every year. By eliminating the streptococcus we should expect a diminished activity of the pneumococcus.

Picric Acid Poisoning.—T. Koizami produced experimentally acute and chronic picric acid poisoning in rabbits and dogs. The acute poisoning gives rise to gastritis, nephritis, various hemorrhages, and abortion. The chronic poisoning causes diarrhea, loss of appetite, and albuminuria. The organism is able to convert picric acid into picramic acid which is nontoxic, and also into compounds containing sulphur and compounds containing glycocoll. Industrial picric acid poisoning has been observed in the laborers in powder factories, the symptoms being gastrointestinal irritation, conjunctivitis, and rhinitis; and picric, and more particularly picramic, acid being found in the urine.—*Sei-i-Kwai Medical Journal.*

A NEW VISUAL LITHOTRITE.

By JULIUS LONDON, M.D.,

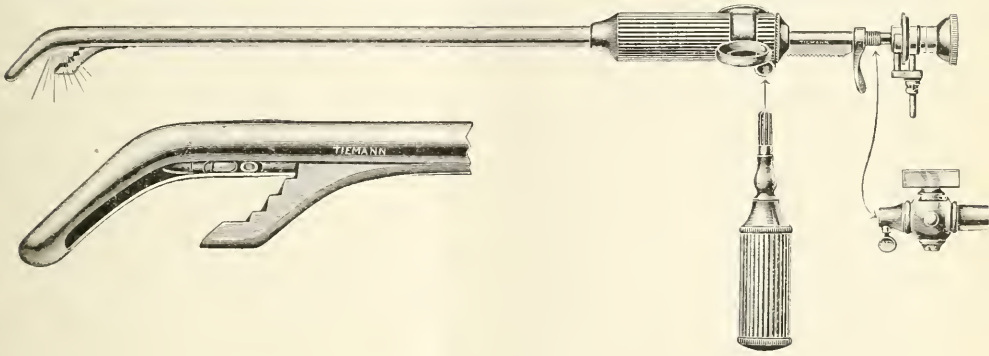
NEW YORK.

CHIEF, GENITOURINARY CLINIC, LEBANON HOSPITAL DISPENSARY; ASSISTANT, GENITOURINARY CLINIC, MT. SINAI HOSPITAL DISPENSARY.

In this preliminary report I desire to describe a visual lithotrite which I have devised and which consists of a cystoscope and a lithotrite with their respective accessories.

General considerations of lithotrites: Before describing my special device, I believe it best to undertake a review of the basic principles on which lithotrites are constructed. A lithotrite is an instrument used for crushing stone in the bladder; it is shaped like a curved sound, and composed of two blades, one, the outer or female blade, and the other, the inner or male blade. When the instrument is closed, the curved extremity is called the beak; the main body of the instrument is called the shaft, while the terminal portion by which the instrument is held is called the handle.

The female or outer blade is deeply grooved for the reception of the inner or male blade. When the latter is slightly withdrawn the beak opens and the halves are called jaws.



London's Visual Lithotrite

Depending upon the character of the work required of them, the jaws vary both in strength and construction. For fragmenting large, hard stone the male jaw has been made narrow with the idea of forcing its way through a stone which could not be penetrated by a wide blade. If the male blade have a toothed surface, each of the several projections will exert an effective wedgelike action on the calculus, and the fragments resulting will be discharged laterally. The female blade should be broad and heavy enough to stand the strain thrown upon it. For the purpose of crushing soft or small calculi or fragments, the jaws of the lithotrite are shorter, less heavy, and their opposing surfaces simply roughened. To prevent impaction of crushed material between the jaws of the lithotrite several expedients have been employed, the most important being the complete fenestration of the female blade, so that the crushed mass could be pushed right through the beak when the male blade was driven home. The objection raised against this fenestration is the resultant weakness of the jaw, especially when the stone is grasped on only one edge, as then the torsional strain on the female jaw is supported by only one bar, while if the female jaw is only partly fenestrated, the metal between the two edges acts as a buttress and distributes the strain to the entire jaw.

To obtain the advantages of the solid blade and to provide against impaction, the female blade has been made partially fenestrated at its base, with a corresponding spur on the male blade to clear the jaws on closure.

From the very first introduction of lithotrity, which was the forerunner of litholapaxy, the value of having control over the amount of fluid in the bladder was recognized and sporadic use was made of a hollow blade to accomplish this purpose. This received its highest development at the hands of Chismore, who not only crushed fragments, but also aspirated them through his lithotrite.

It should also be noted that numerous attempts have been made to employ visual control of the operation of litholapaxy, to which I beg leave to contribute my feeble efforts. In my lithotrite I employ two principles which I believe are fundamental in making for success in this work; these are: (1) A large size lithotrite. My present model is 30 French. (2) Making the opening in the male blade as small as possible, as the mechanical strength of the lithotrite varies directly as the cube of the thickness of the metal.

In discussing the lithotrite which I have devised we shall consider first the component parts and then the entire instrument assembled.

The male blade is 15½ inches long, tubular in character, the bore admitting a cystoscope size 15 French. Upon its upper surface the shaft is strengthened by a bar which terminates at its distal extremity in the male jaw. This is one inch in height, placed at an obtuse angle to the shaft, and terminates in a projection which is parallel to the base line and extends for three-eighths inch beyond the body of the jaw. Thus we see that the male jaw has a gooseneck appearance, the shaft of the blade corresponding to the body of the bird, the body of the jaw corresponding to the neck, and the projecting terminal tip to the head and bill of the bird.

At this point I desire to call particular attention to the fact that there is no spur at the base line of the male jaw. When we shall take up the use of the cystoscope through the lithotrite, the great importance of the removal of this spur in allowing us to retain a most comprehensive visual control of the entire male jaw at all times will be apparent. In order to obtain the wedge action so important in crushing large and hard stone, the

body of the jaw carries six alternating triangular notches, three on either side. The terminal projection is obliquely cut at its distal end in order that this also may exert a wedgelike action. At the proximal end of the shaft of the male blade the bar is thicker and carries a ratchet which is worked by a pinion. A small bar is also attached at this proximal end to serve as a thumb rest.

The female blade is composed of a tubular shaft 10½ inches long, a cylindrical handle at its proximal end and at its distal end the female jaw. This is a deep hollow, strengthened by a heavy metal back, in which there are two perforations, one at the base of the shaft, which is contiguous with the opening in the male blade, and the other near the tip, into which the projecting tooth of the male blade fits when the instrument is closed. To accommodate this projecting end on the male jaw, the terminal extremity of the female jaw is curved forward slightly, so that the increased diameter thus obtained can be supported by a solid metal tip. The handle is cylindrical in form, has a ring on either side to serve as a finger rest and a guard over the site of the ratchet for the pinion to work in.

When the lithotrite is closed, it is 16 inches long, 30 French in circumference, and has the appearance of a curved metal catheter, the opening through the male blade being contiguous to and in a straight line with the opening at the base of the female jaw. It is thus apparent that when the lithotrite is introduced into the bladder, this continuous channel will allow of free irrigation and distention of the bladder by fluid introduced through the instrument itself without removing it. By means of an aspirator attached to the stop cock the smaller fragments may be removed through this channel. If fragments become impacted at the base of the jaw, a stilet may be inserted to dislodge them. When only the front part of the jaws are in opposition, there is quite a fenestrum between the main bodies of the respective jaws, and the cystoscope can actually study the toothed surface of the male jaw in its entirety even with the terminal parts of the jaws touching. Furthermore through this fenestrum the bladder walls may be observed to make sure not to pinch them between the blades. This lateral fenestrum allows the fragments to discharge laterally while the two perforations in the female jaw afford additional facilities to prevent impaction.

Now we come to the joint use of lithotrite and cystoscope. After the lithotrite has been introduced into the bladder, the latter is distended with fluid introduced through the channel above described and the cystoscope, previously tested on the rheostat is inserted. In the first position the beak of the lithotrite points upwards with its jaws closed, while the cystoscope projects beyond the opening in the female blade and explores the bladder. When the stone is located, the beak is turned sideways, opened over the site of the calculus, and the latter is grasped. The cystoscope is slightly withdrawn and then the mechanical power, in form of rack and pinion, is applied. The instrument has a crushing power of (200) two hundred pounds. In applying the power, the beak is turned sideways or downwards, and the pinion inserted on the right side and rotated clockwise, as this is the most natural movement of the wrist.

The cystoscope is arranged on a straight stem, with a working length of (16) sixteen inches, it is 15 French in circumference. The distal extremity contains the lamp which is of the cold type; the objective has a focus of one and one-half inches with its axis directed (15) fifteen degrees forward from the right angle. The telescopic system conforms to the latest principles of geometrical optics, is of the double inversion type, and gives a corrected image. The electric connection is a sliding contact.

The mechanical features of my lithotrite are thus seen to be:

1. A large sized instrument with the smallest feasible bore for the cystoscope; this gives a large volume of metal to stand any reasonable strain thrown upon it.

2. The visual control of the male jaw is absolute even when the front parts of the blades are in contact.

3. Simplicity of construction and ease of application of mechanical power.

The lens system was made by Wappler and the lithotrite by Tiemann.

616 Madison Avenue.

Medicolegal Notes.

Practicing Suggestive Therapeutics Without a Certificate.—The Washington statute, Rem. and Bal. Code, section 8400, provides that "any person who shall practice or attempt to practice, or hold himself out as practicing medicine and surgery, osteopathy, or any other system or mode of treating the sick or afflicted in this state, without having, at the time of so doing, a valid, unrevoked certificate from the State Medical Board, shall be guilty of a misdemeanor. In criminal proceedings for practicing suggestive therapeutics without having such a certificate the defendant argued that this provision denies to those persons engaged in the practice of any system or mode of treatment not embraced within the terms "medicine," "surgery," and "osteopathy," as mentioned in the section, the equal protection of the law, in establishing an arbitrary classification and denying to those not within such classification the right to engage in a lawful contention. The same argument was made by the defendant in State v. Greiner, 63 Wash. 46, 114 Pac. 897, where the defendant was convicted of practicing chiropractic without a license, but the contention was not sustained. The court followed the Greiner case.

Suggestive therapeutics was held not to be the practice of any religious, nor "any kind of treatment by prayer." As practiced by the defendant it consisted of a laying on of hands upon that part of the body where the trouble is and "upon certain parts of the spine that control the nerves, or the nerves that control the organ," and giving certain suggestions which pass from the healer's mind to the mind of the patient, resulting in "certain vibrations" being sent through the body that are instrumental in effecting the cure. It was held that this brought the defendant within the act.—State v. Pratt, Washington Supreme Court, 141 Pac. 318.

Increase of State Health Officer's Salary.—Action was brought by the state of Alabama against the state health officer to recover the sum of $2,333.10 claimed to have been paid him by the state board of health in excess of his salary authorized by law. The Alabama Code 1907, § 698, provides that the State Medical Association shall constitute the state board of health. Section 704 declares that such board shall elect the state health officer, and fix his term and salary, provided that the salary shall not exceed $5,000 per annum; that such officer, under the direction of the state board, shall exercise general supervision over the county boards of health and county and municipal health officers. It was held that the state health officer, while an officer of the board, was not a state, county, or municipal officer within Const. 1901, § 281, providing that the salary of any officer holding a civil office of profit under the state, county, or municipality shall not be increased or diminished during the term for which he shall have been elected or appointed—State v. Sanders, Alabama Supreme Court, 65 So. 378.

MEDICAL RECORD.

THE WORK OF THE UNITED STATES PUBLIC HEALTH SERVICE.

THE report of Surgeon General Blue of the United States Public Health Service for 1914 has been published recently and provides even more satisfactory reading than usual. In consequence of the appropriation by Congress of a fund for field investigation of public health matters the scope of the work of the Service has been considerably enlarged. The administrative supervision of the work is conducted through the seven divisions of the bureau as follows: (1) Scientific research and sanitation; (2) Foreign and insular quarantine and immigration; (3) Interstate quarantine; (4) Sanitary reports and statistics; (5) Marine hospitals and relief; (6) Personnel and accounts; (7) Miscellaneous. In the limited space at disposal it would be impossible adequately to discuss the report in detail, so it must suffice to pass briefly in review the more important features of that part of the report devoted to the consideration of the work done and in progress by the Division of Scientific Research and Sanitation.

As mentioned before, the Division of Scientific Research, owing to the granting of increased funds, has been very actively engaged during the year in investigations in connection with public health matters. Among the diseases investigated in the several laboratories and in the field during the year were beriberi, diphtheria, endemic goiter, hookworm disease, leprosy, typhoid fever, malaria, pellagra, trachoma, tuberculosis, typhus fever, and certain occupaticnal diseases. In addition systematic investigations of rural sanitation, school hygiene, industrial hygiene, and health organization and administration were taken up and enlarged.

The investigations of water supplies and sewage have included three distinct lines of study, namely, pollution of rivers and coastal waters, disposal of sewage, and treatment of industrial wastes. Among the most interesting studies undertaken was that of endemic goiter in the Appalachian Mountain region. Of 13,836 school children examined in West Virginia and Virginia by Dr. I. Clark, 1,234 cases of goiter were found, or 8.91 per cent. In Virginia of 6,432 school children examined 817 cases of goiter, or 12.7 per cent. were detected. Of these cases less than one-tenth of 1 per cent. was among school boys, girls being mostly affected. As a result of his studies Dr. Clark was inclined to conclude that the extensive prevalence of the disease in rural communities, where families are widely separated and have different water supplies, tends to preclude the possibility of the infection being due to a water-borne living excitant. It can, however, bear some relation to the water supplies, there being a possibility that the affection is caused by a deficiency of certain chemical substances.

The investigations regarding malaria were widespread and in keeping with the gravity of the situation with respect to this national problem. The plan of campaign decided upon against this disease was (1) to make the communities visited understand the situation, and (2) to give practical advice to correct the defects noted. Trachoma is prevalent in several of the Southern States and especially in Kentucky. Dr. John McMullen has been sent to Kentucky to direct operations for the treatment and prevention of the disease. In view of the fact that trachoma is essentially a surgical disease, it has been found necessary to establish hospitals for the treatment of patients. These have proved very successful, but more are needed. The prevention of trachoma is practically synonymous with education in regard to the importance of sanitation, fresh air, and dietetics. Accordingly the service has taken steps to disseminate such information far and wide.

As in former years special attention has been paid by the service to typhoid fever studies. Although the prevalence of the disease in the United States appears to be undergoing a gradual reduction, this country still holds an unenviable position in this respect. The typhoid fever investigations of the Service during the year have been concerned with both urban and rural conditions. Improved sanitation has been mainly responsible for the decrease of the disease in cities, but in rural districts generally conditions favorable to its spread exist. "In fact the sanitation of rural communities is one of the most important problems of the nation." City methods of sanitation are not feasible in country districts and thus rural sanitation depends for its advancement largely upon the observance and practice of sanitary principles by the individual citizens. In order to inculcate into the minds of country dwellers the importance of the observance and practice of these principles, they must be educated in this direction. The Public Health Service is conducting an educational campaign of this description. Work in connection with the study of leprosy has been carried on during the year at Kalilu and at Kalawao, Hawaii.

The above is a necessarily inadequate and incomplete survey of the work performed by the service and recorded in its report for the year 1914. The Public Health Service of this country has done and is doing extremely valuable work in the interests of the health of the community at large. That its labors are appreciated by the public and the medical profession is sufficiently shown by the keen interest taken in the literature sent out under its auspices and by the fact that its educational influence has borne and is bearing fruit.

THE PRESERVATION OF SERA INTENDED FOR INTRASPINAL USE.

The intraspinal administration of sera is not entirely free from danger since a few deaths have occurred which can apparently be blamed on the serum alone. This fact of course does not detract from the great value of such sera in the treatment of disease, notably meningitis. Nevertheless an earnest attempt has been made to determine what factor can be held responsible for these unfortunate results. The first explanation advanced was that the serum had been injected in too large quantities or too rapidly and that the ill effects were the results of increase in the intraspinous pressure. Within the last two years, however, another explanation has been advanced and vigorously urged by one group of investigators. They admit that increased pressure has its influence but hold the opinion, and support it with experimental evidence, that the chief cause of the collapse that may appear is not this pressure but the presence in the serum of a preservative, usually tricresol in a strength of three-tenths per cent. This preservative when brought into direct contact with the respiratory center is apparently much more toxic than when introduced into the circulation and is thought to produce a paralysis of that center. Hale has suggested that chloroform be used instead of any of the phenol group.

The subject is of great importance since intraspinal medication is coming more and more into use with the introduction of the newer remedies and with the recognition of the fact that few drugs introduced into the circulation are secreted into the spinal canal. Auer has been carrying out experiments recently in an effort to establish the action of these preservatives. He used (*Jour. Exper. Med.*, 1915, xxi, 43) dogs and monkeys for this purpose, anesthetizing them by his method of intratracheal insufflation. Injections were always given by syringe in order to approximate average clinical conditions. Briefly stated, he found that intraspinal injections of sera, with or without preservatives, produced qualitatively the same effects upon the medullary centers in the monkey and the dog. The effects differed quantitatively "with the preservative employed, with the dosage, and with the species of animal used, the monkey being strikingly more resistent than the dog. . . . The respiration is first increased both in amplitude and rate for a short period of time then, particularly in the dog, the amplitude decreases and the rate slows and the respiration may even stop for a shorter or longer period of time. The blood pressure shows an initial rise followed by a gradual drop of varying degree." Because he used the intratracheal insufflation method he was able promptly to institute artificial respiration and thus was able to revive his animals in a comparatively short time—twelve minutes in a severe case. Since spontaneous respiration was established so quickly, Auer thinks that the effect on the respiratory center is not paralysis but inhibition, essentially a very different process. In the monkey the effect of the preservative was much less, the results being due, apparently, largely to pressure, since the symptoms were quickly relieved when the fluid was permitted to escape from the spinal canal. In spite of this fact, absorption of fluid from the spinal canal in monkeys seems to take place with remarkable rapidity, since one animal weighing only 2,835 grams received on one day 15 c.c. of chloroform serum and 6 c.c. of tricresol serum, and on the next day 21 c.c. of chloroform serum, 23 c.c. of tricresol serum, and 10 c.c. of Ringer's solution without showing any ill effects. Auer is of the opinion that ether or chloroform would be a better preservative for such sera. Not only is their effect much less depressing, so far as one can judge from a study of the respiration and blood pressure, but also they can be largely removed by warming the serum before use. A separate series of experiments demonstrated that 0.3 per cent. tricresol, 0.3 per cent. chloroform, and 0.3 per cent. ether affected the opsonin content about equally when tested after one week, one month, and three months, so that it may be assumed that the effectiveness of the serum as a therapeutic agent would be the same with any of these substances. He closes with this exceedingly wise advice: "When intraspinal injections are given in the human being it would seem advisable to be prepared to withdraw part of the injected fluid and to administer artificial respiration if necessary. For a safe withdrawal of fluid the gravity method is best; for artificial respiration Meltzer's apparatus for pharyngeal insufflation is recommended."

INCREASING TRACHOMA.

Over four years ago we had occasion to refer in these columns to the increase of trachoma in Cuba since the conclusion of the Spanish-American War. (Medical Record, December 23, 1911.) From the data available at that writing it appeared that immigration had been an important factor in this increase. Since then other reports from widely different sections of North America make it seem likely that the disease is spreading in a manner to warrant the conclusion that other factors more important than immigration are concerned. Thus King (Public Health Reports, Dec. 18, 1914), in giving the result of his investigations among the school children of Porto Rico, notes a rapid increase of late years which is in nowise attributable to immigration. He thinks one of the potent factors in this increase has been the fact that the school system has expanded from an enrollment of 26,000 in 1899 to 182,766 in 1913-1914, thus bringing thousands of school children into close association who would otherwise scarcely have been thrown together at all.

That this cannot be the only factor in the spread of the disease is shown by the fact that it scarcely enters at all into the situation in the continental United States. Thus the recent increase of trachoma in the mountain regions of Kentucky, Tennessee, and Virginia has not been accompanied by a corresponding increase in attendance upon the rural schools. Neither has immigration been a factor in these regions. From a study of all the avail-

able reports it would seem that about the only conclusion as yet warranted is that trachoma is on the increase throughout North America and the West Indies, but that the cause of this increase has not yet been accurately determined. In the meantime a careful search for details concerning the so-called ravages of the disease fails to discover great cause for alarm. All the investigators apparently agree that the majority of the persons found afflicted are free from annoying subjective symptoms of any kind, and it would seem that serious complications such as pannus and ectropion, with their resulting impairment to vision, are chiefly encountered among the very dirty and ignorant classes.

The more we read the reports of the investigators the more we are impressed with the idea that the purely sociological aspects of trachoma loom larger than the strictly medical.

INCOAGULABILITY OF THE BLOOD IN HEMOPTYSIS.

In 1913 E. Magnus-Alsleben reported the observation that occasionally the blood expectorated by tuberculous patients fails to a greater or lesser extent to clot. Others have since noted the same phenomenon. The blood thus expectorated contains several clotted particles, and the fluid portion remains fluid in spite of the addition of calcium salts, serum, and tissue extracts. Blood extracted from the patient's arm shows at the same time the normal power of coagulation. Small quantities of normal blood added to hemoptysis blood have no effect in exciting the coagulation of the latter, while large quantities of normal blood, equal in amount to one-half of the hemoptysis blood, cause a delayed coagulation.

In the *Zeitschrift für klinische Medizin*, Vol. 81, Nos. 1 and 2, Magnus-Alsleben reports the results of his further experiments along this line. He finds that the saliva is not responsible for this inhibition of the power of coagulation of hemoptysis blood. The saliva, as well as extracts of body organs and tissues with the exception of the female genitalia, tends to promote coagulation. On the other hand, products of the autolysis of organs inhibit coagulation. Extracts of diseased organs tend to retard coagulation, just like the autolysates of healthy organs.

The above results seem to suggest that during the course of tuberculosis there are formed in the lung substances that inhibit coagulation. It has been shown by a number of investigators that blood which has been retained in the pleural cavity for a short time or which has been allowed to flow slowly over the surface of a lung, loses the power of coagulation. The cause of this phenomenon is as yet veiled in obscurity. It is quite probable that the same factor which is present when the autolysate of healthy lung retards coagulation is also operative in the case of the inhibition of this power when blood is in contact with the pleural endothelium. In the former case, however, the effect is one of mere retardation, while in the latter case the effect is one of absolute inhibition. The phenomenon observed in the case of hemoptysis blood is one of inhibition rather than of retardation.

Beriberi and White Bread.

Over two years ago Little described a form of neuritis which is fairly prevalent in Newfoundland and on the coast of Labrador where many of the natives live on a restricted diet consisting largely of highly milled white flour. Little, at that time and again later, was of the opinion that the disease was true beriberi, and more recently Ohler (*Jour. Med. Research*, 1914, xxxi, 239) reports experimental results that bear out Little's conclusions. Ohler fed chickens on various diets over fairly long periods of time and found that when the food consisted exclusively of white bread, either with or without yeast, hominy, or milled rice, the fowls developed polyneuritis gallinarum in from five to six weeks. On a diet consisting of whole wheat bread or of wheat grains, or even if cracked corn or wheat was given once a week to birds on the white bread diet, they remained apparently perfectly well, and on autopsy showed none of the signs of the disease. Two birds that were starved for thirty-eight and fifty-six days respectively failed to show typical symptoms or postmortem findings. It is of course not settled that beriberi and polyneuritis gallinarum are identical diseases, but it would seem that the two conditions are sufficiently alike in their course and etiology to permit of satisfactory conclusions. The evidence certainly seems to point to the fact that white bread as a sole article of diet is undesirable in that it apparently is lacking in the necessary vitamines. It does not, of course, demonstrate that white bread is undesirable when taken in conjunction with other articles of food which will supply the missing vitamines. The evidence has gradually accumulated, and this work has added to it, to prove that beriberi is definitely one of the "deficiency diseases," and that the question of its complete eradication is merely one of the supply of the proper food in the districts in which the disease is prevalent, together with the persuasion of the people (not always an easy matter) to use the food thus supplied.

Diagnosis of Typhoid Fever in the Field.

The necessity for a rapid and accurate diagnosis of typhoid fever at the front gives a good opportunity to estimate the value of the tests employed in civil and hospital practice. In the military supplement to the *Muenchener medizinische Wochenschrift*, December 8, Rhein announces his experience in 100 cases of this fever, and is so satisfied with urinary tests that he is silent as to serodiagnosis. Ehrlich's original diazo test is too complicated for employment here, but Weiss' modified diazo reaction is not open to this objection. To perform this the urine is so diluted that its color almost disappears. To this dilution (usually effected by adding from 2 to 3 parts of water) from 3 to 10 drops of a 1 1000 sol. of potassium permanganate are added. If the resulting reaction is positive, a distinct golden yellow coloration appears, due to oxidation of the urochromogen, a normal constituent of the urine. In negative outcome we see either no color change or a slight brownish coloration. In all cases in which the old diazo reaction can be obtained the Weiss modification above described invariably holds good. In doubtful cases (of which there were 10 per cent.) with the original diazo, the Weiss diazo was positive. The author believes that the latter resource can be still further simplified.

The Medical Reserve Corps.

In Great Britain, at the present time, the lack of trained army surgeons is considerably felt. With all the good will in the world it is impossible for a civilian practitioner to be able to fulfill the duties which fall to the lot of an army surgeon without some experience of such duties. In the *Military Surgeon* for December, 1914, Dr. Henry C. Coe, of the Medical Reserve Corps, U. S. A., makes a final protest against the inactivity of the Medical Reserve Corps as at present constituted and conducted. He points out that a certain amount of training yearly is indispensable to fit a civilian for an army surgeon's work, which training the members of the Reserve Corps do not receive. Attention is also drawn to the fact that the government should take cognizance of the existing unsatisfactory state of affairs and see to it that the Medical Reserve Corps should receive as adequate training as is possible.

News of the Week.

Relief for Belgian Physicians.—Dr. F. F. Simpson, treasurer of the Committee of American Physicians for the Aid of the Belgian Profession, makes the following report for the week ending January 23, 1915. Diplomatic arrangements have just been completed whereby drugs and instruments for civilian physicians may be sent into Belgium. Recent advices from Dr. Herbert Spencer of London show that our Belgian colleagues are literally starving. Three hundred additional boxes of food have therefore been purchased at a cost of $660.00. The following contributions have been received during the week:

Dr. W. A. Coventry, Duluth, Minn.	$10.00
Dr. A. William Reggio, Boston, Mass.	25.00
Dr. Edward B. Heckel, Fittsburgh, Pa.	25.00
Dr. T. R. Williams, Punxsutawney, Pa.	10.00
Dr. J. Knox Simpson, Jacksonville, Fla.	10.00
Sonoma Co. Medical Society, Sebastapol, Cal.	50.00
Anonymous—E., Pittsburgh, Pa.	10.00
Dr. A. B. Hirsh, Philadelphia, Pa.	5.00
Dr. Henry Eastman, Pittsburgh, Pa.	10.00
Dr. H. S. Steensland, Syracuse, N. Y.	2.00
Washington Co. Medical Soc., Marietta, Ohio.	25.00
Dr. Lewis S. Pilcher, Brooklyn, N. Y.	25.00
Dr. M. Iverson, Stoughton, Wis.	5.00
Dr. A. H. Traver, Albany, N. Y.	5.00
Dr. Carl B. Drake, St. Paul, Minn.	5.00
Dr. Leonard Freeman, Denver, Colo.	5.00
Dr. Howard C. Taylor, New York, N. Y.	25.00
Dr. Walter F. Donaldson, Pittsburgh, Pa.	5.00
Deer Lodge Co. Medical Soc., Anaconda, Montana.	75.00
Dr. W. S. Zibberman, Spartansburg, S. C.	10.00
Dr. H. MacVicker Smith, Pittsburgh, Pa.	5.00
Dr. Ethel D. Brown, New York, N. Y.	5.00
Dr. Brown Pusey, Chicago, Ill.	25.00
Total	$377.00
Previously reported receipts	1,414.00
Total receipts	$1,791.00
Previously reported disbursements $990.00	
Disbursements week ending Jan. 23 660.00	
Total disbursements	1,650.00
Balance	$141.00

To Abolish Medical License Examinations.—Announcement is made that a bill is to be introduced into the Nebraska legislature permitting graduates of the medical department of the State University and of Creighton University to practise in the State without the formality of an examination by the examining board.

Physician Fined for Neglecting a Court Summons.—A judgment was recently obtained against a physician of this city and as it was not satisfied the doctor was ordered to present himself in court to be examined in supplementary proceedings. He failed to appear, offering as an excuse that his work at the clinic was of so urgent a character that he could not neglect it. The judge held that the excuse was invalid and fined the physician $100 for contempt of court and threatened to imprison him if the fine was not paid within thirty days.

Opposed to Compulsory Vaccination.—A bill has been introduced into the New Hampshire legislature repealing all the sections of the public statutes relating to the compulsory vaccination of school children. It is naturally opposed by the physicians and health officers of the State as well as by all others whose mental faculties are sufficiently nimble to enable them to appreciate the relation of cause and effect.

Trade in Blood.—The therapeutic resort to transfusion is becoming so frequent in the hospitals of this city as well as in private practice, that there is getting to be quite a demand for healthy donors. Several college students are said to have received lately from $25 to $50 for eight ounces of blood.

Chicago Woman Physician in the Belgian Red Cross.—It is stated in the *Women's Medical Journal* that Dr. Caroline Hedger, formerly in charge of the infant welfare work in Chicago, and her assistant, Miss Janet Hall, have sailed for Belgium, to take charge of the work of caring for homeless children, under the Belgian Red Cross. The Chicago Women's Club paid the expenses of Dr. Hedger and her assistant. They carried with them 10,000 doses of typhoid vaccine, donated by a Chicago woman physician, 10,000 vaccine needles, and $700 worth of dressings given by the Red Cross.

Prizes Offered for Motor Ambulance Designs.—Mr. Henry S. Wellcome, founder of the Wellcome Bureau of Scientific Research, in London, has announced that the bureau will provide the sum of £2,000 to be distributed in the form of prizes for the best plans and designs of a body for, and improvements in, field motor-ambulances. The sum mentioned will be divided into a first prize of £1,000, a second prize of £500, a third prize of £300, and the remaining £200 will be awarded in smaller sums. The first three prizes are for a complete design of an ambulance-body which will carry, in comfort and safety, four wounded lying on stretchers of British Army regulation pattern, or eight wounded sitting, or two lying and four sitting, in addition to the driver and orderly attendant. The body must fit a standard pattern motor-chassis for field motor ambulances. The Commission reserves the right to award the whole or any part of the remaining £200 for details, such as an ingenious method of springing, an invention which could be applied to any motor-chassis, an ingenious method of storing arms and equipment, a novel system of lighting, mechanical devices for self-haulage, etc. The competing designs must be received by the Commission not later than June 30, 1915. All details of conditions may be obtained from the Secretary of the Ambulance Construction Commission, 10 Henrietta street, Cavendish Square, London, W. The competition is open to citizens of all nations.

Examination of Dentists for the U. S. Army.—The Surgeon-General of the Army announces that examinations for the appointment of acting dental surgeons will be held at Fort Slocum, New York; Columbus Barracks, Ohio; Jefferson Barracks, Missouri; Fort Logan, Colorado, and Fort McDowell, California, on Monday, April 12, 1915. Application blanks and full information concerning these examinations can be procured by ad-

dressing the "Surgeon General, U S. Army, Washington, D. C." Acting dental surgeons are employed under a three years' contract, at the rate of $150 per month, with traveling allowances. After three years' service, if found qualified, they are promoted to the grade of dental surgeon with the rank of first lieutenant, and receive thereafter the pay and allowances appertaining to that rank. Applications must be in the possession of the Surgeon-General at least two weeks before the date of examination. There will be nine vacancies to be filled.

Physician Fined for Neglecting to Register Births.—At the instance of the Board of Health of New York City a physician has been fined $100 for failing to register the birth of a child within the limit of ten days. The defendant claimed that he did not have the first name of the child, and as the custom in the Hebrew faith is to withhold the naming of a child until after circumcision, this fact prevented him from filing said birth within the prescribed time. The court, however, held that this was not a valid excuse, as the certificate could have been filed without the given name, the latter being added by the parents later, and as this was not the first offense the extreme penalty was enforced.

A New Medical Society.—On January 12 a number of physicians resident in Charlevoix, Antrim, and Emmet counties, Michigan, met at Petoskey and established the Tri-County Medical Society. The officers of the Emmet County Society were continued as officers of the new organization. These are: *President*, Dr. Moorman of Pellston; *Secretary-Treasurer*, Dr. G. W. Nihart of Petoskey.

Hospital Notes.—A bill has been introduced in the Nebraska legislature appropriating $150,000 for the construction of a hospital to be under control of the Omaha Medical College, the medical department of the State University.

The Mountainview County Tuberculosis Sanatorium of Tacoma, Wash., was opened on January 11, thirty patients being admitted.

Fire in the upholstery shop of the State Hospital at Elgin, Ills., early in the morning of January 16 caused some alarm to the inmates, but there was no panic and all responded promptly to the orders of the fire drill, leaving the building without disorder. The fire was extinguished without having done much damage.

Removals.—Dr. Sigmund Epstein of this city has removed to 15 West Forty-fourth street.

Dr. Max Strunsky of this city has removed to 236 West Seventieth street.

Smallpox in Vienna.—A despatch from Rome says that hemorrhagic smallpox is spreading alarmingly in Vienna. Within a week, it is asserted, 151 fatal cases have been reported.

Proposed Change in the Massachusetts Registration Law.—The Massachusetts Board of Registration, in its latest annual report, urges an amendment to the medical license law, making the possession of a medical degree from a reputable college approved by the Board a prerequisite to admission to examination for a license to practise medicine.

The Cutter Lectures in Preventive Medicine for the year 1915 will be given at the Harvard Medical School by Dr. Victor C. Vaughan, Professor of Hygiene and Physiological Chemistry and Dean of the School of Medicine and Surgery of the University of Michigan, and Dr. Joseph Goldberger, Surgeon, United States Public Health Service, Washington, D. C. Dr. Vaughan will lecture on "The Phenomena of Infection" on April 14, 15, and 16. Dr. Goldberger's subject will be "Diet and Pellagra," and will be given in one lecture on April 2. These lectures are given annually under the terms of a bequest from John Clarence Cutter, whose will provided that the lectures so given should be styled the Cutter Lectures on Preventive Medicine, and that they should be delivered in Boston, and be free to the medical profession and the press. Others interested are cordially invited.

Harvey Society Lecture.—The seventh lecture of the Harvey Society course will be delivered on January 30 at 8:30 P.M. in the New York Academy of Medicine, by Dr. Hans Zinsser, Professor of Bacteriology, Columbia University. The title of the lecture will be "The More Recent Developments in the Study of Anaphylactic Phenomena."

The Late Dr. L. Bolton Bangs.—The following memorial was adopted at a stated meeting of the Medical Society of the County of New York, December 28, 1914: "In the death of Dr. L. Bolton Bangs, on October 4 last, the medical profession has lost a notably representative member, and the community a sterling citizen who stood high in the esteem of his contemporaries everywhere. Dr. Bangs was graduated from the College of Physicians and Surgeons, New York, in 1872. After serving on the interne staff of Bellevue Hospital he and the late Dr. William T. Bull, always close friends, studied together in Vienna and in Berlin. On his return he became associated with the late Dr. Fessenden N. Otis, thus becoming identified with the pioneer period of genitourinary surgery in this country, long before the science and art of urology had been developed or had even begun to be differentiated from the then more comprehensive field. Dr. Bangs wrote but little in the early part of his career; apparently he waited until an accumulated experience could furnish material for his papers and give weight to his conclusions. A remarkably keen and discriminating power of clinical observation, made that accumulated experience noteworthy and won for his writings a deserved recognition. In 1898, in collaboration with Dr. W. A. Hardaway, he edited the 'American Text-Book of Genito-Urinary Diseases, Syphilis, and Diseases of the Skin.'

"Hospital appointments and official positions in various medical societies were given to Dr. Bangs in no moderate measure. At the time of his death he was consulting surgeon to five hospitals in Greater New York, and was an Emeritus Professor of the New York Post-Graduate Medical School and Hospital. The constructive character of his work during the years of his active connection with that institute as the Professor of Genito-Urinary Surgery from 1889 to 1894, will live in it forever, though the sacrifices he made for its welfare have become somewhat forgotten in the intervening years. From 1898 to 1901 Dr. Bangs was professor of Genito-Urinary Surgery in the University and Bellevue Hospital Medical School. In deference to his health he resigned—much to the regret of all, both faculty and student body.

"Always an enthusiastic worker, and enjoying the inspiration that teaching gave him, he threw himself so completely into the careful preparation and presentation of his lectures and clinics that he won the admiration, regard, and responding enthusiasm of his students, both postgraduate and

undergraduate. It was said of him: 'His skill and knowledge are unquestionable, and, in addition, he has that rare quality of a successful man—modesty.' To this we may add: 'He was resolute, moderate, clear of envy, yet not wanting in that finer ambition which makes men great and pure.' Alert, resourceful, quick to perceive and to comprehend, apt in illustration, fluent in speech and elegant in diction, generous, sympathetic, whole-hearted, high-minded, and clean, no wonder that friends, the associates in his office, students, and patients admired and loved him. During the last three years of his life he worked on, giving comfort in mind and body to many; but the loss to himself in physical and mental energy was greater than could be restored. As was his wish, he died in harness.

"Such were the career and the personality of him whom we do well to honor as we can and may this evening. Absorbed by his profession and jealous of its reputation; devoted to his patients and unsparing of himself, both brain and body, for their sakes, he was the ideal physician in that he taught the youth, ministered to the sick, and did well his part to sustain a high standard of intelligence, of culture, and of ethics within and without the profession. Your committee, therefore, would resolve, that in these or some similar words, The Medical Society of the County of New York record its appreciation of Dr. L. Bolton Bangs, the man, the physician, and the teacher, and that it expresses thereby its sense of the loss it and the profession have sustained by his death. Your committee would further resolve that this tribute be spread upon the minutes and that the secretary be instructed to forward a copy to the bereaved family."

Signed: James Pedersen, *Chairman*, Joseph B. Bissell, James R. Hayden.

This memorial was adopted also at a stated meeting of the New York Urological Society, on December 2, 1914, and at a stated meeting of the Genito-Urinary Section, New York Academy of Medicine, on December 16, 1914.

The Late Dr. H. Seymour Houghton.—The following minutes were adopted at a stated meeting of the Medical Society of the County of New York on Monday evening, December 28, 1914: "During a period of seven years it was the good fortune of our Society to have the official help of Dr. H. Seymour Houghton. He served as a member of the Committee on Discipline, as second vice-president, as first vice-president, as president, as chairman of the Board of Censors, and as a member of that Board. During this period problems of great gravity arose. It was necessary to hold protracted and oft-repeated committee conferences and special meetings of the Society itself were held. The well-being of members of the Society and the dignity of the profession, as represented in the Society, were in large measure dependent upon the way in which these problems were met. Dr. Houghton gave to this work a combination of good qualities which is seldom found: absolute integrity, sound judgment, broad sympathy, great executive ability, high professional attainment. These qualities were unsparingly given to the Society. But for his magnanimous nature and his far-seeing judgment, the troublous times in which he labored might have been far more disturbing for the Society and the profession which it represents.

"The individual members of the Society are sad in the loss of a warm personal friend, and the Society as a whole sorrows at the loss of a most valuable officer and adviser. It is the wish of the Society to record its feeling of sadness and to express to the members of Dr. Houghton's family its heartfelt sympathy."

Signed: Charles N. Dowd, M.D., *Chairman*, Brooks H. Wells, M.D., Charles G. Kerley, M.D.

Obituary Notes.—Dr. Levi Francis Warner of New York, formerly a Civil Service Medical Examiner, and one of the Board of Police Surgeons, died in St. Luke's Hospital on January 20 after a short illness, aged 50 years. Dr. Warner was graduated from Williams College in 1885, and from the College of Physicians and Surgeons, New York, in 1889. He was physician-in-chief to the New York Dispensary for a number of years, and was a member of the American Medical Association, the New York State and County Medical Societies, and the Alumni of St. Luke's Hospital, and visiting physician to St. Francis Hospital.

Dr. John D. Cronmiller, for 55 years a practitioner at Laurel, Md., died at Baltimore, on January 4, at the age of 82 years. He was graduated from the University of Maryland School of Medicine in the class of 1857.

Dr. William P. White of Louisville, Ky., a graduate of the University of Louisville, Medical Department, in 1869, a member of the Confederate Army, serving throughout the Civil War, and formerly health officer of Louisville, died at his home, from pneumonia, on December 27, aged 71 years.

Dr. Walter De Witt Boggs of Altadena, Cal., a graduate of the Long Island College Hospital, Brooklyn, in 1910, died at his home on January 5, aged 32 years.

Dr. Charles Smith of Riverside, Conn., a graduate of the Long Island College Hospital, Brooklyn, in 1890, and a member of the American Medical Association and the Connecticut State and Fairfield County Medical Societies, died at his home on January 8, aged 45 years.

Dr. Thomas Smith Middleton of Chicago, Ill., died at the home of his son, Dr. Claude R. Middleton, at Mount Hope, Pa., on December 29, at the age of 47 years. He was graduated from the Medico-Chirurgical College of Philadelphia in the class of 1897.

Dr. John Harry Swaving died of apoplexy at Pottsville, Pa., on December 30 at the age of 48 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1889. He was a member of the Schuylkill County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. William James Allen died of nephritis at Landisburg, Pa., on January 2, at the age of 54 years. He was graduated from the Baltimore University School of Medicine in the class of 1886. He was a member of the Medical Society of the State of Pennsylvania and the Perry County Medical Society.

Dr. Charles Barclay Warder died of heart disease at Philadelphia on January 5 at the age of 51 years. He was graduated from Jefferson Medical College in the class of 1885 and from the medical department of the University of Pennsylvania in the class of 1888. He was at one time Medical Director and a member of the Board of Managers of the John B. Stetson Hospital.

Correspondence.

A NEW AND GREATLY SIMPLIFIED METHOD OF BLOOD TRANSFUSION.

To the Editor of the Medical Record:

Sir:—In my article with the above title published in the Medical Record last week, the following paragraph in reference to Dr. Weil's use of sodium citrate was omitted:

"Dr. Weil stated that he used 1 c.c. of 10 per cent. solution of sodium citrate to 10 c.c. of blood and had transfused citrated blood up to 250 c.c. This dose, however, is from my experiments entirely too big and might prove to be a toxic dose in the average transfusion of 1200 c.c."

R. Lewisohn, M. D.

OUR LONDON LETTER

(From Our Regular Correspondent.)

1915—NEW YEAR'S HONORS—B. P. CHANGES NOW IN FORCE — PROFESSIONAL SECRECY — OPIUM SMUGGLING — TYPHOID INOCULATION — BEIT FELLOWSHIPS—OBITUARY.

London, January 8, 1915.

1915—the date is becoming familiar. In the New Year's honors list the profession obtains a P. C., a C. M. G., some representatives in the new decoration (the Military Cross), some Indian and sanitary distinctions, besides knighthoods.

The new B. P., so we speak of the new edition of the pharmacopœia, is now in full force and prescriptions are required to be written and dispensed according to it, unless distinctly otherwise ordered. I have previously reported its main changes, but may refer again to one or two of the most important. The additional drugs inserted number 43, but the omissions are 168; of the later the active principles of some are substituted. Changes in strength of powerful medicines are more likely to give rise to errors, and so are demanding more attention. Tr. Opii is one-third stronger, and being sold as laudanum to the public has often been the cause of fatal poisoning, and as often the profession has urged that its sale should be restricted. This will be in some degree accomplished by the change, for the increase of strength removes it from one schedule to another under the Poisons Act, and consequently requires the vendor to take additional precautions and enter every sale in a special book with the purchaser's signature. Tr. Aconiti is twice as strong and Tr. Strophanthi four times, as formerly. On the other hand, Tr. Digitalis is reduced by 20 per cent. and Tr. Nucis Vomicæ by 50 per cent. Metric notation is recognized for those who prefer it, and will perhaps gradually come into use. A number of drugs which have been largely prescribed under trade names are among the additions under their chemical names, *e.g.* aspirin (acetylsalicylic acid).

The annual report of the Medical Officer of the Local Government Board was issued on Monday. During the year 1913-14 no fewer than 284,668 pathological specimens were examined on behalf of various local authorities. This is equivalent to 7.71 per 1,000 of the populations concerned. The expenditure in the same year on the laboratories where this work was carried out is stated to have been above £23,000 or £1 per 1,600 persons in the populations. But Manchester is said to have spent £1 per 337 and Sheffield £1 per 339 of their respective populations. In England and Wales the hospitals and other institutions providing medical treatment for the sick number approximately 2,233, having a total of 214,069 beds, or 1 bed per 168 of the population. The Poor Law Infirmaries are not included in the foregoing figures. The number of these beds devoted to infectious diseases is stated as 28,105. In lunatic asylums there are 109,024; in institutions for the feeble-minded, 11,559, and in consumption hospitals an uncertain number provided by local authorities.

The doctor's secret is an expression often used to signify what is rather his patient's secret, and most medical men in the course of practice become acquainted with facts that they have no right and no wish to divulge. The honor of the doctor is involved, and no class of men is more scrupulous in that respect. Now and then, however, the question as to whether a higher duty than that due to the patient can supersede it becomes a burden to the doctor, and the point has been discussed from time to time for many generations. It has always been held that in ordinary circumstances the medical man must maintain inviolate a secret entrusted to him or which has become otherwise known to him in the course of the practice of his profession. The law admits the obligation, but seems to limit it as to grave criminality. The strongest case is that of murder, a knowdelge of which may be discovered by him unintentionally or may conceivably be confessed to him in the course of his attendance. This is an extreme case and so unlikely to occur as to suggest mental aberration in the self-accuser. There would be other considerations, but the main one is whether duty to the State ought to supersede duty to the patient, and, if so, at what point, for obviously the extent to which an individual might be involved in any act differs enormously, as also does the degree of criminality. In regard to less grave crimes the variations will be greater, as may also the opinions formed, although it may be held that the same principles should rule all cases.

This subject has just been revived by Mr. Justice Avory in charging a jury on the case of a woman accused of murder by inducing abortion. This eminent judge, taking what may perhaps be termed without prejudice the legal view, laid down that in such circumstances it was the duty of the medical man to communicate with the police. The deceased clearly died as the result of an illegal operation. Three medical men attended her and to one at least she confided the name of the person who performed the act. No information was given. The woman died without any deposition being taken or any statement made on her death-bed which could be used in a court of law. "No one," declared the learned judge, "would wish to see disturbed the confidential relation which exists, and which must exist, between the medical man and his patient," but he added there are cases in which the "time to preserve that confidence must be subordinated to the duty cast upon every good citizen to assist in the investigation of a serious crime, such as is imputed to this woman."

This general statement is causing no little discussion among medical men, not a few of whom maintain that it goes beyond, if not in opposition to, the traditions of the profession—traditions which have been recognized by other judges, among whom Hawkins is constantly quoted. Others are ready to endorse Mr. Justice Avory's remarks to their full extent. The difference is reflected in our medical

journals, and it seems probable that no settlement of the matter will be reached, but after the vain effort to elucidate it we shall find ourselves as uncertain as heretofore—each man obliged to follow the dictates of his own conscience as to his duty in each individual case he may be called upon to determine.

A report of the Colonial office issued this week refers to the efforts to check the smuggling of opium out of Hong Kong to countries which prohibit the importation of the drug. The governor of the colony pronounces the policy of controlling the sale of morphine, cocaine, and other preparations, which was maintained throughout the year 1913, to have been successful. Over 5,580 ounces of morphine and over 1,760 of cocaine were seized during the year, all destined for China or neighboring ports.

Answering a question last night in the Upper House, the Lord Chancellor said that inoculation against typhoid was not compulsory but the medical authorities were so convinced of its benefit and placed such stress upon it that of two men who wished to see active service the one who elected to be inoculated would be preferred to the one who declined.

The trustees of the Beit Memorial Fellowships for Medical Research have elected Drs. E. G. Fernsides, E. P. Poulton and Mary Gore Micklethwaite to the Fellowship; each is conducting research in London hospitals. Each Fellowship is of the annual value of £250 and the tenure is usually for three years. In exceptional circumstances the trustees have power to grant an extension for a fourth year.

The death is reported, on the 19th of December, of Dr. Klaus Hanssen, of Bergen, where he was chief physician to the municipal hospital and whose work in connection with tuberculosis made him known through other countries.

Mr. Thos. Bryant, the venerable consulting surgeon to Guy's Hospital, with which as student and surgeon he was connected throughout his life, died the latter part of December, aged 86. He was Surgeon Extraordinary to Queen Victoria and Surgeon in Ordinary to King Edward. He took the membership of the Royal College of Surgeons in 1849. Four years later he passed to the Fellowship. Subsequently he was elected a member of the council and in due course of the Court of Examiners. In 1890 he was chosen as president of the college and in two subsequent years was re-elected to that office. During his surgeoncy at Guy's he occupied the chair of surgery for thirteen terms. After thirty years' service at the hospital he was made consultant.

In the course of his career he was president of several societies, among them the Royal Society of Medicine, the Clinical, the Hunterian, and the Medical Society of London.

His "Practice of Surgery" was for many a year a favorite text book. His "Diseases of the Breast" and his "Intestinal Growths" will be also known to you as will his Lettsomian, Hunterian, and Harveian lectures.

Fleet Surgeon H. Harrison Smith, M.D., St. And., 1848, R. N., died January 4, aged 90. He joined the Naval Medical Service in 1848 and retired in 1870. He was awarded a Greenwich Hospital Pension in 1888.

Sir Robert M. Simon, M.D., F.R.C.P., J.P., physician to the Birmingham General Hospital, died December 22, aged 64. He was a Cambridge graduate, where he became at one time an examiner, an office he also filled at the Birmingham University. In 1910 he was knighted. He was a magistrate for Warwickshire as well as for the city, where he spent so much of his life. Last year on resigning his hospital appointment after 35 years' service, he was presented with an address and his portrait, which hangs in the Board room. You may know his "Ingleby Lectures on the Common Skin Diseases." He also wrote some articles on "Brass Founders' Ague."

Col. William Johnstone, C.B., M.D., R.A.M.C., retired, died Dec. 26, aged 71. He entered the army in 1865, served in the Transvaal in 1878, and took part in the Zulu war, 1879-80. He retired in 1892, but was recalled during the South African war and served as assistant director of the Medical Department at the War Office.

6. The Treatment of Pneumonia in Children. Report of 104 Consecutive Cases. H. W. Dana.

1. Pregnancy Following Ovarian Transplantation.—M. Storer presents an interesting discussion of this subject. He states that a dozen or more cases have been reported of pregnancy following the grafting of the ovary into the uterine wall of an individual in whom the tubes had been occluded or removed. There have been reported three cases of living children born as the result of the heterografting and three or four pregnancies terminating in miscarriage as the result of the same procedure. In these cases of heterografting one must face the suspicion that a tiny piece of the original ovary may have been left behind. The author reports the case of a woman, aged twenty-four, who had both tubes and one ovary removed on account of an acute gonorrheal salpingitis of a month's duration. The author transplanted the single ovary into the uterine wall. Sixteen months later there were definite signs of pregnancy, but the patient miscarried at three and a half months.

2. The Epilepsy of Dostojewsky.—L. Pierce Clark analyzes the life and writings of the late Russian novelist, Dostojewsky, as a contribution in support of the author's theory that the essential defect in the epileptic makeup is in the affective sphere of the mind in which there exists an emotional infantilism due to a defect in the development of the psychosexual life. The settings of the epileptic fit suggest that the latter represents an unconscious desire to return to the state of the libido comparable to that of the culmination of the sexual act.

1. Modernized Proctology.—S. G. Gant states that

the common practise of purging patients the night before operation ensures that the field of operation will be bathed with liquid feces, which delays the work, contaminates the wound, soils the dressings, and makes the patient uncomfortable subsequently. In simple operations on the rectum, as for hemorrhoids, fissure, fissure and polyp but a few minutes are required to prepare the patient. Eight ounces of soapsuds are injected into the rectum to bring away the solid feces, after which the mucosa is mopped over with peroxide of hydrogen or other antiseptic. Local anesthesia is dependable, is indicated in 75 per cent. of all rectal operations, and is best accomplished by means of a 0.12 per cent. solution of eucaine. In the postoperative treatment the author keeps his patients on a normal diet, does not order a laxative unless the stools show a tendency to hardness, when he prescribes mineral oil, fruit, or other laxative. The practice of universally cauterizing wounds no longer obtains; they are drained and not packed. If healing is tardy, wounds are stimulated by leaving in contact with them a gauze pledget moistened in a solution of silver nitrate, 6 per cent.; ichthyol, 10 per cent., or balsam of Peru, 20 per cent. The rational treatment of strictures to-day consists in dividing them under local anesthesia when low down, excising the affected gut when higher up, or performing colostomy in inoperable cases. In the treatment of fistula proctalopists prevent fecal incontinence by dividing the anal muscle at a right angle, draining instead of packing the wound, and by trimming off the mucous membrane or skin edges so that they do not project into the wound and prevent union of the sphincter ends. The author's method of treating fissure consists in splitting the anal canal under eucaine anesthesia. Uncomplicated thrombotic hemorrhoids can be laid open, cutaneous hemorrhoids excised, and internal hemorrhoids radically operated upon under local anesthesia.

6. **For Better, for Worse.**—C. H. Duncan uses this title for his thesis that certain phenomena observed in the breeding of animals are applicable to the human species, namely, the impregnated woman acquires certain physical and mental attributes of her consort. Children by a second husband sometimes have features resembling those of a first husband. There is a strong featural resemblance between couples who have been married for many years. In thoroughbred horses the colt by a second stud is said to have "a drop of cold blood in his veins" if the mare ever had had a colt by an inferior stud. The author advances the view that during copulation the female absorbs, in addition to the generative cells, certain elements from the spermatic fluid, which elements have a decided effect in improving her own health and also to a certain extent in molding her to conform to the physical and mental status of the male partner. This line of reasoning suggests the thought that there may possibly be some therapeutic justification for the use of testicular extracts in the treatment of some of the functional disturbances of celibate women.

1. **Operations for Brain Tumor.**—Harvey Cushing is of the conviction that to group together all the operations for all tumors which arise anywhere in the cranial chamber and to consider percentages gained by such a process, is largely a waste of time and a possible abuse of figures. Unquestionably the time has come to concentrate upon individual lesions in individual situations if, through comparative studies, one is to increase technical facilities and improve mortality results. Specialization with some knowledge of neurology; skilled assistance, for intracranial operations are not star performances, familiarity with the safe and respectful handling of the central nervous tissues, which is best acquired by the experiences of the experimental laboratory; and painstaking, scrupulous technique are the chief elements of success. An observance of these things will not make more tumors accessible, but it will permit the removal of those that are accessible to be more often accomplished and render those that are not, capable in a larger percentage of cases of being safely palliated.

2. **Extraperitoneal Cesarean Section.**—G. Gellhorn points out that the classical Cesarean section and its modifications are adapted only for cases in which there is no infection, in which the membranes are intact or recently ruptured, and in which previous examinations and attempts at delivery have been strictly avoided. In the so-called "unclean" cases the extraperitoneal operation originated by Thomas in 1870 and recently rehabilitated by Frank is the operation of choice. It is to make an incision into the lower uterine segment instead of the fundus, and to exclude the operative field from the rest of the peritoneal cavity. It has not fully fulfilled the hopes it excited, and patients already infected cannot be saved by it. Brilliant results, however, are obtained in suspected cases, and even more so when the operation is employed in aseptic ones. The author gives the details of three cases, and describes the technique used. It is, strictly speaking, a transperitoneal method. The parietal peritoneum is first incised, then the visceral peritoneum is pushed off the lower uterine segment, and finally, by stretching the parietal peritoneum to the uterus, the free abdominal cavity is excluded, and the operation rendered extraperitoneal. In the classical Cesarean section there are, beside the scar and adhesions, copious bleeding during the operation, the escape of amniotic fluid and meconium into the peritoneal cavity during the section, and the possible leakage of uterine fluid later on. In the extraperitoneal method the postoperative adhesions are not conceivable and the temporary protection of the abdominal cavity by suturing the parietal peritoneum to the uterus prevents the escape of fluids. After the operation the parietal peritoneum completely covers the field, and the contractions of the uterus cause the peritoneal sutures to disappear, leaving an unbroken peritoneal surface. There is only one condition in which the extraperitoneal method does not offer advantages over the others, and that is in

placenta praevia. In such a case the incision through the lower uterine segment would open the enormous dilating blood sinuses, which would render orientation and proper check of the hemorrhage difficult.

7. **Traumatic Coxa Vara.**—A. Steindler reports ten cases of this condition in children in which the cause assigned was traumatic separation of the epiphysis. At a certain period, say from the ninth to the sixteenth year, epiphyseal separation may occur with or without a preexisting or coexisting rickets, and may be followed by a deformity known as coxa vara adolescentium. The casual trauma may be and often is slight. The loss of function in these cases is never absolute or immediate, except in cases of great violence or injury. The points of significance for diagnosis are as follows: Injury to the hip of moderate extent, such as a fall or wrench; an intermediate period of functional freedom; no or very mild subjective symptoms; the late and gradual development of the coxa vara deformity with increasing disability, and the age of the patient. The author does not believe that absolute reliance can be placed on the *x*-ray evidence, inasmuch as very slight lesions will not show any more than they do in injuries to the spine which are followed by Kümmel's post-traumatic kyphosis.

The Lancet.

January 9, 1915.

1. A Communication Between the Two Ventricles of the Heart Occupying an Unusual Situation. T. Wardrop Griffith.
2. Some Conditions that Simuate Chronic Appendicitis. J. Morley.
3. Pneumoperitoneum of Three Days' Duration Following Resection of a Carcinomatous Rectum; Evacuation of the Gas and of a Pelvic Abscess; Recovery; No Recurrence After Five Years. J. D. Malcolm.
4. Osteoplastic Resection of the Skull in Decompression Operations on the Brain. S. Mort.
5. A Third Outbreak of Epidemic Poliomyelitis at West Kirby. G. Jubb.
6. Anteriovenous Aneurysm of the Femoral Vessels, Following Bullet Wound Through the Left Thigh. W. M. Willis.
7. The Value of Tuberculin as an Addition to Sanatorium Treatment. N. D. Bardswell.
8. Leper Houses and Mediæval Hospitals. C. A. Mercier.

1. Unusual Communication between Cardiac Ventricles.—T. Wardrop Griffith describes the anomaly found in the heart of a man who had died at the age of 30. The abnormal opening between the ventricles did not occupy the site usual in such malformations, but was farther forward under the aortic cusp from which the right coronary artery opens. The explanation of this anomaly is apparently found in the hypothesis of the dual origin of the right ventricle, which is said to develop from two chambers—the ventricle proper and the bulbus cordis. The interventricular septum has similarly a double origin, which accounts for two different types of openings between the ventricles.

2. Conditions Simulating Chronic Appendicitis.—J. Morley believes that Lane's ileal band, apart from inflammatory changes that may occur in it incidentally, is of little or no importance in the occurrence of disease, and that the many ingenious operations devised for dealing with it are the outcome of misdirected enthusiasm. Jackson's pericolic membrane may, however, give rise to symptoms simulating chronic appendicitis, though less commonly than many who write on this subject would have one suppose. In the greater number of these cases the symptoms are due not to the membrane but by the abnormal mobility of the cecum and ascending colon. Inflammatory bands are not rarely met with in the region of the cecum, both as a result of old-standing appendicitis and as a sequel of former tuberculous inflammation. Perhaps the commonest cause of an erroneous diagnosis of chronic appendicitis, the author says, is right chronic tuboovarian disease.

3. Pneumoperitoneum.—J. D. Malcolm reports the case of a woman, aged 60, in whom three days following the resection of a carcinomatous rectum, there developed pneumoperitoneum. Recovery followed evacuation of the gas and of a pelvic abscess, and there was no recurrence of malignancy after five years. The interest of this case lies chiefly in the pneumoperitoneum. It is inconceivable to the author that gas could escape from the intestine into the peritoneal cavity through any opening, however small, during a period of three days without an escape of organisms which would induce a general peritonitis. There is also no evidence that gas can escape through the wall of the healthy intestine, and it would seem therefore that the gas developed in the peritoneal cavity, which could occur only from the action of some aerogenic organism. Many descriptions of such organisms have been published, but only two are generally recognized as producing gases in the tissues apart from putrefactive changes. These are the *Bacillus aerogenes capsulatus* of Welch and the *Bacillus œdematis aerobius* of Sanfelice.

4. A Decompression Operation.—S. Mort has devised an operation which is described as a preliminary resection of a flap of soft tissue and bone in the usual way; this is followed up by "pepper pot" trephining of the flap raised. This can be done effectively and quickly with a burr, perforations three-eighths to one-half inch in diameter being drilled at close intervals from the interior of the reflected plaque, right through the osseous tissue, but not including the soft parts. The bone flap will then be a sort of retaining cage of a basket-like, fenestrated, or pepper-pot texture. This cage, the author thinks, should efficiently retain the brain without risk of hernia and yet with satisfactory relief from pressure.

British Medical Journal.

1. Nerve Concussion Due to Bullet and Shell Wounds. A. H. Tubby.
2. The Treatment of Infantile Paralysis: A Study in Biology. W. MacKenzie.
3. A Field Hospital in Belgium. J. H. Beavis and H. S. Souttar.
4. Anomalous Case of Enteric in an Inoculated Subject. E. A. Bourke and S. Rowland.
5. Appendicitis Treated with Anticolon-Bacillus Serum and Vaccine. A. Cowan Guthrie.
6. The Warble-Fly—Hypoderma. A. E. Shipley.
7. Medical Work in the Early Seventies in a County Infirmary in Ulster. G. St. George.

1. Nerve Concussion Due to Bullet and Shell Wounds.—A. H. Tubby defines nerve concussion as a damage to a nerve trunk without actual destruction of the axis cylinders; the damage consisting in an effusion of blood between the fibers, following compression of the nerve against a bone by the rapid passage of a foreign body in the immediate neighborhood of the nerve; or the damage may not amount to hemorrhage, being a mere anemia or hyperemia of the nerve. As the result of the lesion there is a partial and irregular paralysis or paresis of the muscles supplied by one nerve trunk. But complete recovery of power, the author says, usually ensues within a short time after the receipt of the injury.

2. Treatment of Infantile Paralysis.—W. MacKenzie recommends the use, in the early stage of this condition, of thymus extract, in daily doses of 15 to 20 grains to a child, basing this practice upon the fact that the thymus gland is at its maximum when muscular action and co-ordination are developing. This treatment is merely accessory to the basic measure, rest, which must be immediate. After the acute stage the paralyzed muscles must be re-educated along the line of the acquisition of their proper function.

4. **Typhoid Fever Following Antityphoid Inoculation.**—E. A. Bourke and S. Rowland report the case of a British private who had been vaccinated against typhoid fever in March, 1914, and again on November 10, 1914, just three days previous to his admission to the hospital. There was a history of three days' malaise; blood culture was negative; a few days later the temperature became normal, and on November 19 the patient was discharged for observation. Two days later he was readmitted, complaining of slight headache, slight cough, and pains in joints; he had had a chill just previous to admission. The temperature was 104°; the pulse 92, and the respirations were 32. There was a slight, transient patch of bronchopneumonia. No other physical signs developed. For two weeks the temperature oscillated between 100° and 104°, when it dropped to 97°. It then rose to 99° to 102° for two weeks, after which it remained at 97° to 98°. During the last week he had several rigors, followed by cyanosis and signs of heart failure. He had slight pyorrhea, which improved under treatment. During the second and third week of his illness he had slight diarrhea, which was not typhoid-like. Emaciation, especially towards the end, was a marked feature of his illness. During the first four weeks the pulse remained between 80 and 90, but for the last week it rose to 100 to 110. Blood cultures made on November 14, 24, and December 4, were all negative. The diagnosis was not established until December 21, when examination of the urine showed it to be full of typhoid bacilli in agglutinated clumps. On December 22 the patient had two hemorrhages from the bowel; the blood was bright red. There was never any abdominal tenderness or distention, and no splenic enlargement; and there were no rose spots; moreover, except during the first few days there was no headache and the tongue remained clean throughout. The patient died from heart failure on December 24. The mind remained clear up to the end. On post-mortem examination about a dozen typical typhoid ulcers, mostly healing, were found in the ileum; all other organs were healthy. Typhoid bacilli were recovered from the gall bladder which contained a rich, pure culture of these microorganisms.

5. **Appendicitis Treated with Anticolon-Bacillus Serum and Vaccine.**—A. Cowan Guthrie has employed this method in 22 cases which apparently recovered without the necessity of operative measures. Most of the cases were in the acute stage; a few of the patients showed symptoms of chronic appendicits; and in one patient there was pain in the cecal region for two years after the appendix had been removed. The author's method of treatment was based upon the supposition that appendicitis may be due in some measure to infection by the *Bacillus coli*. The most suitable dose was found to be 20 c.c. anticolon-bacillus serum; 10 c.c. should be injected subcutaneously first in the right and then in the left hypochondriac region. A few days later 100 million colon-bacillus vaccine should be injected in a similar way into the deltoid region. This is supposed to prevent recurrence. As organisms other than the *B. coli* may be the determining cause of this disease, the "fixation of complement test" should be tried, using the patient's serum and the most probable organism (*B. coli*, pneumococcus, streptococcus), a corresponding serum or vaccine being used. The anticolon-bacillus serum is supposed to act chiefly as an antitoxin, also as a counterirritant, causing local leucocytosis. It has also probably a physical effect, changing the equilibrium in the surrounding fluids and thereby producing increased osmotic pressure and favoring phagocytosis of the bacilli, as has been shown by Leduc.

New Facts About Old Opium Alkaloids.—Pohl devotes his attention chiefly to papaverine and narcotine. The latter must not be confounded with "narcophin," which is a mixture of narcotine, morphine and meconic acid. The art of potentization of opium alkaloids by mixing them in various proportions is an outgrowth of Bürgli's well-known method of prescribing, which has given the author contradictory results. Of isolated narcotine we know that it relaxes the isolated intestinal musculature if injected into the peritoneal cavity; and that in large quantities it stimulates the respiration. Of far more significance is papaverine, which has been studied as thoroughly by Pal and others. In 1904 the author discovered that this alkaloid can lower the temperature. Small doses paralyze the intestine, but do not seem to check diarrhea. We know that a small addition of codeine greatly enhances the action of morphine on the bowel. As papaverine is enabled to relax the intestine, the drug was tested on the excited uterus, and Halban has recently checked an abortion with papaverine. To a certain extent papaverine resembles atropine in its action on the bowel, although much less toxic; and is also in part antagonistic to adrenalin. It lowers the blood pressure from the very outset, and has been tested with doubtful results in conditions accompanied by high blood pressure. Pal recommends it in angina pectoris. The problem of the field of papaverine in therapy is of unusual interest, because the German army must economize on morphine, and this is practicable only when substitutes are able to fill some of its indications. Can papaverine be of service here? There is rapidly acquired tolerance for this drug, as is the case with morphine. Papaverine is probably decomposed *in toto* in the organism, save when large fatal doses are given, in which case some of the drug appears in the feces. To conclude, what we know of papaverine leads us to believe that it can relax smooth muscle fiber to a variable degree, and as soon as the doses and mode of administration, synergists, etc., can be worked out for mankind, the author says, the drug should be found of value and do some of the work of morphine.

Vascular Suture in Military Surgery.—Jeger has performed suture of blood vessels eight times upon wounded in the fortress of Przemysl. The author had but recently published a classical work on blood vessel surgery. His present paper was carried to Berlin by an aviator. Authorities in general hold that blood vessel suture is indicated in war service in but a very small proportion of cases, because as a primary operation it is impracticable in dressing stations and field hospitals, and even if this were not the case there are contraindications. The author agrees with this in the main, and especially when it concerns those without the necessary technical skill. Yet he was able in five of his eight cases to save the patients' limbs. In one case which parallels one recently reported from Bucharest, the arm was almost totally detached, and required reimplantation as well as vascular suture. These two cases (author's and Janu's) seem to represent in actual practice that which Carrel and other students of expérimental vascular surgery have pronounced almost impossible. The author did no harm whatever, for in one of his eight cases the conditions made suture an impossibility, while a second patient died of an intercurrent complication. A third case did fairly well but finally came to secondary amputation. End to end anastomosis was done six times, lateral anastomosis twice.

Diseases of the Circulatory Organs in Warfare.—Grober, now at Metz, considers the effects of warfare on the presumably healthy circulation of the soldier. These begin notably among the older men during mobilization. The overexertion and hardships of warfare tend to fatigue the circulation and reveal the existence of "inferior" heart and blood vessels—in other words, cardiac weakness. The affected subjects may be quite unaware of their condition. The pulse is small, weak and slow, inferentially with very low blood pressure. Anhythmia was not noted. The cardiac area was amplified without lowering of apex beat. The impression made was that of a dilated left ventricle. Sudden movement after rest may cause murmurs. Heart morbidity in civil practice is not encountered in warfare save in rare instances. Typhoid fever occurring in troops, and, perhaps, dysentery, injure the myocardium. Damage to the heart by way of the nervous system is naturally expressed in various ways, as in civil practice. Psychic trauma caused an acceleration of pulse up to 140 and profuse sweats. Arteriosclerosis is naturally to be expected after the war, and this is a predominant fear. The Germans, and especially the French, are seeking to prevent this condition by using prophylactics like potassium iodide. The author does not believe in this possibility. Treatment of weak circulation in troops in the military hospitals consists chefly of personal hygiene, notably rest. The soldiers usually go back to the front after three weeks.

Treatment of Senile Gangrene with Ultraviolet Rays.—Kriser has recently been using the "artificial high sun," otherwise the Bach-Nagelschmidt modification of the Kromayer Quarzlamp, in some miscellaneous surgical cases and tested the resource incidentally on a case of senile gangrene, due to arteriosclerosis in a sixty-year-old subject. The gangrene had been preceded for months by severe pains in the limb, and was spreading over the foot so that it was clearly an amputation case. Prolonged raying with actinic rays, varied at times by the warm rays, completely healed the condition in two months. There was almost a complete restitutio ad integrum, the gangrenous areas having been replaced by thin white scars. The rays at first increased the pains, but these exacerbations were followed by remissions. The cure was evidently due largely to the fact that this form of radiation has been known to lower the blood pressure permanently.

The "Artificial High Sun" in Military Medicine.—Thedering first mentions natural high sun exposure, which paved the way for artificial substitutes. Its possibilities were first brought to notice through the brilliant results of Rollier in surgical tuberculosis. Next in order torpid ulcers were made to heal. In the present war it is being used extensively in military hospitals for ragged and gangrenescent wounds. The quartz lamp rays are said to have only a superficial action, but in some cases they may be used in concert with x-rays. Gangrenous sores may be quickly rendered inodorous, probably through ozonization. It has not yet been shown that the artificial solar rays are bactericial.

Treatment of Pneumonia, Pleurisy and Bronchitis with Menthol-Eucalyptol.—Berliner refers chiefly to military morbidity. He has made a trial of this remedy, said to be valuable in the pulmonary infiltrations of tuberculosis, in acute pneumonia at the front. Pohl had succeeded also in showing that menthol is able to control experimental pleurisy. The cases of pneumonia at the front appear as a rule after a sudden chill, followed by fever of 40 deg. They receive daily a gluteal injection of 1 c.c. or a point more of a solution to be described later. The temperature begins to fall soon afterwards, and is often normal by the third day, and the infiltration in many cases can no longer be recognized. The use of the remedy is continued for a week. It has been shown that menthol has properties as a heart stimulant. Professor Küttner of Breslau has used the author's remedy with great success in several cases of postoperative bronchitis. But the promptest results of all are seen in pleurisy. Unfortunately the author's solution is to be kept secret. We know that it contains menthol and eucalyptol, and he confesses that he has improved the original formula by adding a little acetanilid and salicylate of antipyrin. To give a patent for a remedy intended for the defenders of the Empire would seem at least highly unpatriotic, and the author mentions no patent nor manufacturer. Thus far he has only used a name involving probably no proprietary rights. The outbreak of the war has prevented further research, so that the author is by no means ready to report fully on his solution.

Hypodermic Promoters of Peristalsis in the After-treatment of Gynecological Laparotomies.—Frankenstein mentions in this connection atropin, the peristaltic hormone, and the water soluble glucoside obtained from cascara sagrada (which has been marketed for several years under a proprietary name). All these substances are efficacious in postoperative paralysis of the intestine. His paper is written chiefly in the interest of the cascara derivative which he has used in 172 consecutive laparotomies immediately after operation, and with the best results. Similar good results have been obtained from a proprietary derivative of senna, but this is somewhat painful to inject, the author fancies.

Radium Treatment of Cancer.—Rupp sums up as follows: Should we subject to treatment operable or only inoperable cancers? If one could go by certain cases one might say that there is no further use for the knife. For example the author cured a young woman of a very large genital cancer, and in a relatively short time. Bumm, however, has first rayed operable cancers, and then extirpated them, finding cancer cells and nests in active state, although the rays penetrated to a depth of 4-5 cm. Hence, first operate, then radiate. For in theory, at least, we can use this treatment with success in advanced cases. Unfortunately, cancers which readily metastasize, like those of the breast, cannot often be influenced by these measures.

Preventive Measures Against Tetanus.—Hufnagel in a brief communication to the editor records that in the Field Hospital at Namur 2,193 wounded had been received between September 11 and November 30. Of this number 27 developed tetanus. On and after October 15 all wounded received prophylactic injections of serum (20 antitoxin units). From October 15 to November 30 not a single case of tetanus developed in an inoculated subject. The number inoculated was 1,195, the majority of whom were severely injured.

Visceral Lesions Following Acute Pancreas Death.—Carlo Grande finds that in the sudden death resulting from acute lesions in the pancreas or the introduction of its ferments into the peritoneal cavity there are focal lesions in various organs of the body. The nature and distribution of these lesions suggest that pancreas death is the result of an intoxication by proteolytic ferments.—*Archivio per le Scienze Mediche.*

Insurance Medicine.

Life Insurance and the Wassermann Reaction.—Jacobsthal discusses the reaction from a double viewpoint. First, is the patient syphilitic when he applies for insurance; or is he quite free from syphilis? This is a simple problem which may be settled by a simple test. Second, if syphilitic, what is the prognosis, from a simple test and from repeated testing. In the second case an extra premium might be charged if certain standards were respected, as age of patient, date of inspection, length of treatment period, negative Wassermann reaction. The companies, however, would find this too complex to be practicable. A practical routine procedure is to add five years to the age of the syphilitic applicant, suggested evidently by the actuary in estimation of the extra risk. In other words, a man who applies for insurance and has a positive Wassermann reaction pays the premium of a healthy man five years his senior. Overmortality from syphilis is overcorrected by undermortality of the tuberculous, etc. This, however, is not ethical toward the normal policyholder who really pays a tax every time one of these syphilitic risks dies of his disease. But we really know very little about the overmortality from syphilis. It may be much higher than figures show. We cannot tell how much of actual disease, aneurysms, etc., is due to this affection. Syphilis cannot be compared with some of the similar maladies because it is in no way foreordained, and is due to contributory carelessness or something akin to it, which moreover involves a violation of the moral code.

On the other hand it would not be just to refuse syphilitic applicants unconditionally. In the great capitals syphilis is so very common that such a rule would seriously endanger the insurance business. Compulsory Wassermann reaction tests would have ruinous consequences. Besides the syphilitic especially needs insurance, because he is more exposed to premature death, and must provide for his family upon that contingency.

In theory all applicants should be subjected to a Wassermann reaction test, but this is an operation, demands consent from the applicant, and a special fee for the examiner. All this is against the tendency of the day, which is to restrict the medical examiner's activities. The author personally adheres to Schottmüller's viewpoint (already stated in these columns).

The author believes that the luetin reaction of Noguchi will be of use in insurance examinations, inasmuch as in late syphilis it is often positive when the Wassermann reaction is negative.—Blätter für Vertrauensaerzte der Lebensversicherung, 1914, Vol. V, Nos. 4 and 5.

Alcoholism with Reference to Life Expectancy.—Alcoholism presents so many stages or degrees and phases that it is an extremely difficult problem in life insurance. Statistics are very useful when they are founded upon the right basis and the proper premises have been used in their preparation. Patton shows that each individual presents a physiological resistance, different from that of all other individuals, to outside influences and most of them show a varying resistance to different outside influences. An individual's resistance to the same outside influence differs with his age, occupation, state of health, time of day, relative time since food was taken, also the amount and character of the food used, exercise, sleep, and many other conditions. The above statement holds true for alcohol and tobacco. The length of time and amount and frequency of the liquor used have much to do with its systemic effects. The Prudential Life Insurance Company, of which Dr. Patton is the Associate Medical Director, drew the conclusions that the premium charge contemplated the average risk and that this included the moderate drinkers or those who did not exceed Anstie's limit.

Among those who may be regarded as immoderate drinkers are: (a) Those who drink regularly in excess of Anstie's limit or who may, because of individual susceptibilities, be unduly affected by that amount or less. (b) Those who occasionally become hilarious and these, if under twenty-five years of age, should be accepted on some limited plan if found physically satisfactory and careful investigation shows no fixed habit, if they are well established in business or steadily employed, give no history of excess for two years, and are not now drinking beyond the moderate limit. (c) Those drinking to intoxication regularly or periodically should not be accepted. Reformed drunkards or graduates of any cure or institutional treatment as a rule are undesirable risks. If they are considered at all there should have been a lapse of ten years, and the following factors should be kept in mind, viz., applicant's age, social condition and environment, the duration and degree of the habit, thorough investigation by non-medical sources, and a careful report by a competent medical examiner upon the physical and mental conditions, for each individual applicant is a law unto himself. Doubtful cases are to be referred to one of the medical officers for a final decision.

The above methods, Patton says, work very successfully and there are few cases that call for the final decision of a medical officer alone. There is no attempt to divide the cases into abstainer and non-abstainer classes. The Anstie theory referred to is that a certain amount of spirits is harmless and may be consumed in the body with little or no danger, providing the amount is below a certain limit.—Medical Section, American Life Convention.

History Taking in Life Insurance.—Powell tells of a case where a man desired insurance. He was about thirty years of age, present physical condition, habits, and family history were first class; but about eight years ago he was treated for some "stomach" trouble lasting several months, a very indefinite condition. Eight years ago, no recurrence, a man in perfect health at the time of his examination, would any medical examiner lay much stress on such a history? He was unreservedly recommended. The medical directors, however, with their rules of selection desired to know more of this stomach trouble and requested the applicant to obtain a statement from the physician who treated him at the time. The physician lived in another State, but in time a statement was received in which the company was advised that the applicant had been under the care of this physician in an insane asylum for a period of almost a year, and that if he had treated him for stomach trouble it was of such mild and transient character as not to appear in his notes. This shows the value, Powell says, of careful and painstaking history taking.—*Denver Medical Times*, October, 1914.

Book Reviews.

Diseases of the Bones and Joints. By Leonard W. Ely, M.D. Associate Professor of Surgery, Leland Stanford Junior University, San Francisco, Cal. With 95 illustrations. Price, cloth, $2.00. New York: Surgery Publishing Company, 1914.

Ely has long specialized in this field, has done much valuable original work, and is thus well qualified to bring out the important diagnostic and therapeutic points peculiar to diseases of the bones and joints. In addition to possessing the requisite knowledge he is also endowed with the happy faculty of presenting his material in a clear-cut, logical manner, is never verbose, and yet the essential facts are couched in such language as to catch and retain the interest of the reader. In the author's words, "The work represents an effort to present the subject as briefly as possible, dealing with the various diseases, in the matter of space, very much as their relative frequency. It is intended primarily for the general practitioner, but, contrary to custom, instead of furnishing that long-suffering and very important person with a mass of detail, and with many methods of treatment from which he may choose, attempts to lay down broad general principles, with the evidence on which they are based, and then to show how these principles may be applied. * * * The book upholds strongly the idea that a comprehension of the pathology of disease is a prerequisite for treatment." In accordance with this statement he lays the foundation by first describing the anatomy, physiology, and pathology of bone and joints, then proceeds to the discussion of acute arthritis, chronic arthritis of various types, ankylosis, acute and chronic diseases of the shafts, and concludes with a short chapter on new growths in bone. For the benefit of those desiring to pursue any topic further, Ely has given many references in the text and occasionally appended short bibliographies. The illustrations are generally good and the book should appeal strongly to the class for which it was intended and to those who wish to refresh the memory upon essential points without going into too much detail.

Guiding Principles in Surgical Practice. By Frederick-Emil Neef, B.S., M.L., M.D., New York City. Sextodecimo; 180 pages. Price, cloth, $1.50. New York: Surgery Publishing Company, 1914.

This little book conveys just the information that the young operator must have if he is to start right in the practice of surgery. If, as *should* be the case, he has already served as interne on the surgical side of a good hospital, he will find this a most interesting outline for the review of the principles and procedures that he has seen demonstrated during the course of his service; but if one is to attempt surgical work without having had a hospital experience a work of this kind becomes an absolute necessity if disastrous results are to be avoided. In this work we find directions for the preparation of the patient, the preparation of the surgeon and his assistants for aseptic work, the choice and preparation of all the materials used in the operation, such as instruments, suture material, dressings, etc., considerations affecting the choice and method of administering the anesthetic, where and how to make the incision for abdominal and pelvic cases, the steps of the operation, the closure of the incision, the application of dressings, the after care of the patient under varying conditions, and the consideration of many other subjects of equal importance. Generally speaking, the advice is sound; but we deplore the recommendation of chloroform and, above all, anesthol as the anesthetic of choice when ether, especially in inexperienced hands, has been proven beyond question to be infinitely safer. Marginal headings and an exceptionally full index make reference to any particular point easy, but those for whom such a book is suitable should familiarize themselves with its contents from cover to cover.

Bakteriologische Untersuchungen des Keimgehaltes im Genitalkanale der fiebernden Wöchnerinnen mit Berücksichtigung der Gesamtmorbidität im Laufe eines Jahres. By Dr. Maunu af Heurlin. With 3 plates and 17 tables. Price 12 marks. Berlin: S. Karger, 1914.

This work is based on material studied in the well-known clinic at Helsingfors and presents an extended study of the bacterial contents of the genital canal of the puerperal woman with special reference to the morbidity occurring during the subsequent year. From the study of a series of over 2000 cases he found that the total morbidity in the year after delivery was generally higher in summer, but with two well-marked exacerbations during November and December and also in April. Where a genital cause for the fever was found the cases were irregularly distributed through the months; whereas, those in which extragenital infection was present showed a gradual increase from September to April and a corresponding diminution from April to August. The monograph is apparently a very valuable contribution to the always interesting subject of puerperal infection, but it would have been desirable for the author to present his conclusions in a more concise form.

Kurzgefasstes Handbuch der Gesamten Frauenheilkunde; Gynäkologie für den Praktischen Arzt. Edited by Dr. W. Liepmann, Privatdozent für Geburtshilfe und Gynäkologie an der Friedrich-Wilhelm-Universität in Berlin. Bd. II. "Pathologische Anatomie und Histologie der weiblichen Genitalorgane in kurzgefaster Darstellung." By Dr. Oskar Frankl, Laboratoriumsleiter an der k.k.l. Universitätsfrauenklinik (Vorstand Hofrat Schauta) in Wien. With 113 illustrations in the text and 34 colored plates. Price 30 marks. Liepzig: F. C. W. Vogel, 1914.

The present volume is one of six which presents in a very complete form a manual of gynecology and obstetrics by a number of well-known German writers. It is the aim of the editor, Dr. Liepmann of Berlin, to incorporate a consideration of both obstetrics and gynecology in the same work, claiming that this specialty demands a study of all phases of woman's existence, beginning with the differentiation of the sexes and ending with the final stages of her life. He has divided the subject into two main sections, dealing with the anatomy, histology, development, bacteriology, pathological anatomy, and physiology, each in a single monograph, and devoting a separate volume to the technique of operations, diagnosis, therapeutic methods, and dietetics. Two volumes are also given up to the practical aspects of gynecology and obstetrics, which present the modern therapeutic methods in gynecology. This detailed consideration the editors justify by the fact that as a rule insufficient amount of attention is given to the same, either by descriptions or illustrations. The latter have been given particular attention by the editors and are worthy of particular consideration.

The volume herewith referred to deals with the pathological anatomy and histology of the female genital organs in which the various pathological aberrations of uterus, placenta, tubes, ovaries, vagina, perineum, and pelvic connective tissue are considered in great detail and illustrated by a large number of very excellent colored plates. Although unsuited for detailed review, the volume may be commended to the American student for its great attention to detail and the excellence of both text and illustrations. It is unusual in most gynecological manuals for the author to devote the necessary consideration to the obstetrical aspects of the diseases of women, and such works as the present can only serve to accentuate the value and necessity of considering this important topic in a class entirely by itself. Both the editor and the individual contributors to this volume, therefore, deserve particular credit for their labors.

The Philosophy of Radioactivity, or Selective Involution. By Eugene Coleman Savidge, M.D. New York: William R. Jenkins Company, 1914.

The author expounds his philosopsy of the universe. He sees in the spiral nebulæ the process of upbuilding of the radioactive substances going on. These formed, the process of back-swing begins—"matter unwinding to lower density," by successive expulsions of helium atoms, the atomic weight decreasing thus, four at each expulsion. The author opposes to this process, "quality winding to higher velocity," from disparate motions, to auditory qualities, then to visual qualities, ad infinitum.

Into the intracacies of his philosophy, however, we cannot go. The work evinces a comprehensive acquaintance with the literature of radioactivity, and represents a philosophy *sui generis*. The book is not, indeed, altogether easy reading, largely because the author has found it necessary to evolve what almost amounts to a new vocabulary, which until one has mastered it, renders prograss somewhat slow. Nevertheless, in these days when books are largely carpentered together out of other folks' traditional unwisdom, it is refreshing to come across one having the merit of originality.

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Sixty-sixth Regular Meeting, Held Friday, Dec. 4, 1914.

The President, Dr. W. B. James, in the Chair.

Three Interesting Tumors of the Skull.—Dr. Robert Abbe presented these cases. In the first case, a small-celled sarcoma of the skull had disappeared after being one year under radium treatment. The patient, Mr. J., 41 years, builder, had noticed two depressions on the top of his head where he had previously had a blow against a beam, when raising his head suddenly. His surgeon found a soft growth, which on operation was too vascular to be removed. The man was referred to Dr. Abbe for radiotherapy. On operation to remove a piece for examination, he found a soft tumor raising the scalp from the dura, more than an inch and a half. The skull was entirely wanting at the site of the median half of the right parietal bone, and the defect extended across the median line for more than an inch. The diameter of the bone defect was irregularly 2 inches by 4 inches. The edges were sharply punched out. Microscopically the growth was sarcoma of the round cell type. Treatment: radium was at first used externally. Later, it was used through small punctures: long platinum and other tubes of radium were inserted into the soft tumor mass and a simultaneous cross firing was given by external applicators. No severe reaction occurred, but slow subsidence of the growth took place during three following months. The tumor had shown apparent cure during the past year. The dura was now flat and soft with smooth bone edges and no trace of tumor could be discovered. The patient was now in perfect health.

The second patient, Miss D., aged 41, was referred to Dr. Abbe for sarcoma of the upper jaw. A small piece of the tumor had been removed above the gum and was reported osteosarcoma, involving the antrum. Examination showed a great hyperplasia of both alveolar portions of both maxillæ, with exostosis of the front of the right. Incidentally a prominence of the frontal bone and curious twist of the left forearm gave suspicion of Paget's disease. The *x*-ray picture showed great hypertrophy of all the cranial bones and of the left ulna and right femur which were distorted in length and curvature. The right antrum was well opened and cleaned of hypertrophied tissue which was reported to be round cell sarcoma, although the bone showed no sarcoma. A liberal use of radium followed the surgical cleaning out of the cavity and one year later the patient was reported to be in fine health and with no evidence of the disease.

The third patient, Miss R., suffered from a metastatic thyroid cancer of the skull. Since childhood the patient had had a large goiter. For some months she had had two tumors on the skull, one parietal, one frontal. On examination each was found to be the size of a small orange, 3 inches in diameter and two in thickness, firm and vascular in consistency. The bone edge was found to be sloping on to the tumor. The patient was reduced in health. Removal of the parietal tumor was first undertaken and proved to be a very bloody operation. It had entirely replaced the bone and rested on the dura. It contained much bone and was imperfectly removed from the diploetic edges into which it grew. The base had to be curetted from the dura. After due interval to convalesce from the exsanguination, the frontal tumor was removed with the same imperfection. Long spikes of bone grew up through the tumor as well as the granular dissemination through the tumor and showed again the diploetic growth extended beyond the margins of operable tumor. The only hope of benefit lay in the subsequent use of radium. While the wounds were still open a heavy post operative treatment of radium was given, using some 300 milligrams of pure radium bromide. Both wounds healed promptly. The patient's health was perfectly restored and the scars were now soft, smooth and flat. Ten months after radium treatment the patient was still free from any trace of disease. The goiter was no smaller, but Dr. Abbe was endeavoring to influence it by radium without operation unless forced to it by increase. The pathological examination showed a type of cancer of the bone with thyroid structure, and therefore typical metastases.

Dr. Brannan asked if the first patient had ever had any cerebral symptoms.

Dr. Starr asked if the patient had ever had any convulsions; on being told no, he said that the dura could not have been involved.

Dr. Abbe said the patient had never had tingling, numbness, or any cerebral symptoms. Radium had not injured the dura; he had left the radium tube in 21 hours; the tumor had slowly subsided in the course of 3 months; this could be said to be a definite disappearance of a malignant tumor which was rapidly enlarging. A case of Dr. Starr's, on the other hand, a glioma involving the skull, and twice removed from the brain, did not yield to radium treatment; it was a different type of tumor. The small-celled sarcoma yielded to radium treatment.

Dr. Starr said that in this connection he would like to mention a case of his which was very interesting. The patient came to Dr. Starr from Dr. Prout of Summit, suffering from motor aphasia and a slight spasm of the right side of the face and hand. Diagnosis of tumor was evident. Dr. Hartley operated on him at the N. Y. Hospital and found an infiltrating glioma. He did not feel justified in attempting to remove it because he would have had to remove the cortex and the patient would have been deprived of speech and would have had paralysis of the face. The tumor increased in size and 6 months later Dr. Hartley operated again and sliced off a large section, but there was a recurrence. After Dr. Hartley's death Dr. Kenyon operated and removed a portion of the tumor but did not try to take it out because it was so extensive. The wound healed with considerable difficulty. A year later the man came back suffering as before with more paralysis and was quite hemiplegiac, although he was able to come in from New Jersey. Dr. Starr took him one year ago to Dr. Abbe who took an interest in the case. Although the scalp was very thin he thought it better to insert radium tubes into the tumor itself. This was done at St. Luke's Hospital, but the radium did not have any effect. The man grew gradually worse and died last May. Dr. Abbe had treated him 6 months. Dr. Starr had hoped that as this was an infiltrating tumor it might have been successfully treated by radium. In this case it was of interest to know that radium had been thoroughly tried and found to be useless.

Dr. Brannan said that Dr. Abbe had remarked on the vascularity of the tumor in this case. Did that interfere with the insertion of the radium?

Dr. Abbe said he never let bleeding interfere. The pressure of the radium instantly stopped bleeding.

Dr. Brannan asked if the radium did that.

Dr. Abbe said no; it was just the pressure of the tube.

Dr. Thompson said he had seen an interesting case of a parietal tumor in a negro. The *x*-ray showed it to be simply over the external table. It gave no symptoms. The man had had it many years. It was as large and hard as half a billiard ball and produced a very curious deformity of the skull. The cause was unknown. The man had had no injury. The *x*-ray showed it to be simply a bony overgrowth.

Dr. Abbe said that in regard to emanation tubes, which were sometimes used, they were pinhead sized glass bulbs and lost their effect after 4 days. He knew of one reported case of glioma that had been relieved by radium and he would try it again. There were different ways of using it; different quantities and methods. Two points impressed him in these cases: in round-celled sarcomata there was a specific action of the radium in a certain number of cases; and, second, he thought that probably in lymphoid structures there was a greater effect than on fibrous structures. In one of his cases (the cancer of the head), it was a metastases of a thyroid tumor. This was a glandular structure and might more easily yield to radium and might account for this particular type of tumor being relieved. He had had two other cases of round-celled sarcoma of the skull which showed the same good results from radium, but these were complicated by other conditions, which led to a quick ending.

Dr. Starr asked Dr. Abbe if he had had any effect in Graves' disease and thyroid hypertrophy?

Dr. Abbe said he had used it in many cases. He thought it a good way to reduce the gland by fibrosis and atrophy after radiation. In one case recently he inserted two radium tubes into each lobe and left them in two or three hours. He was not prepared yet to report on the many cases he had treated during the

last twelve years. There was one case, an enormous goiter which had disappeared under this treatment nine years ago and had never recurred. After two months the disappearance was absolute and complete.

Pylorectomy for Chronic Perforating Gastric Ulcer; Acute Perforating Duodenal Ulcer.—Dr. GIBSON presented these cases. The first patient, W. P., male, aged 57, was admitted Feb. 9, 1914, to the Surgical Service of the New York Hospital. He had had symptoms referable to the stomach for the past 30 years with constipation, epigastric pain, acid eructations, belching of gas, and at times vomiting. Recently the attacks had come oftener and had been more severe. A year ago a particularly severe attack had lasted three months. Two months ago condition recurred so severely that patient had to give up work. He had lost twenty-five pounds in two months. Physical examination showed a man of emaciated appearance. Inflation of the stomach showed an enormously dilated stomach, the lower border reaching nearly to the pelvis. Gastric analyses showed a great amount of fasting contents with changed blood in large amounts; no free acid; low total acid and presence of lactic acid. Ewald test meals showed little abnormality, but presence of occult blood. *X*-rays showed marked retention at the end of twenty-four hours. A pylorectomy for chronic perforating ulcer of the pylorus with stenosis was performed February 9, 1914. Convalescence was complicated by a biliary fistula, after which the patient improved rapidly. Microscopic examination of the specimen showed no carcinoma. The patient was discharged March 13, 1914, weighing 135 pounds. On October 22, 1914, the patient reported he had gained forty pounds. He was in best of health, strong and vigorous and able to eat anything. He had to use no cathartic. The *x*-ray picture at this time showed good drainage of the stomach; after one hour and a half almost empty; three hours and a half, empty; six hours and a half, stomach empty. Dr. Gibson said the case was reported to illustrate the advantages of believing that a stomach lesion with a history as given should be considered a surgical condition at the outset. The patient's daughter, in this instance, while under treatment by Dr. Gibson, described her father's condition with the request for a recommendation of a stomach specialist. He advised her to bring the patient directly to him and before he saw the man he had an *x*-ray taken. With the facts obtained the diagnosis was complete and no time had to be wasted with unnecessary details.

The second patient, H. D., fifty-one, salesman, was admitted February 11, 1914, with a history of chronic stomach trouble for five years, with increasing severity in the last two years. He had occasional hemorrhages, fourteen in two weeks. He had bad general health. There was a history of lues and alcohol. Onset of present illness began with sudden, severe, cramping pain in epigastrium twenty-four hours previous to admission. He vomited several times. He managed to work some that day. He went to bed that night and next morning had extremely severe pain. He fell on the floor and thought he fainted. On admission a median laparotomy was performed and a duodenal ulcer, juxtapyloric, was found. Closure was satisfactory; no stenosis. There was considerable viscid material in the upper abdomen which was sponged out. The abdomen was closed without drainage. Time of operation was twelve minutes. Convalescence was disturbed by a wound infection. Patient was discharged March 17, 1914. On June 8, 1914, patient reported. He had a sinus leading down to the right about three inches, with a moderate amount of discharge. He felt well and looked well. His tongue was clean and he had gained twenty pounds. On November 23, 1914, the patient's condition was exceedingly good. He had gained forty-seven pounds since the operation.

Dr. GIBSON said he had never felt it necessary to do gastroenterostomy for the cure of the ulcer itself. He did not believe there was enough stenosis occurring to warrant doing gastroenterostomy. He believed it was very seldom indicated. The second case, W. P., he thought at first might be carcinoma of the stomach; however, he had an *x*-ray taken of the man before he even saw him and when the man appeared the diagnosis was made. Dr. Gibson showed a new clamp for gastroenterostomy work. It was more simple and effective, he said, than many enormous clamps he had seen used for many years.

Dr. PECK said he congratulated Dr. Gibson on the brilliant results obtained in his cases.

Dr. BREWER said he agreed with Dr. Gibson in general in not doing a gastroenterostomy for perforation. He did not do gastroenterostomy unless imperative. He had, however, had one case of ulcer of the duodenum in which the involvement was sufficient to make him believe there was stenosis after closure; in this he did gastroenterostomy. In another similar case he did not do it. In the last case the man later had to have gastroenterostomy to save his life. In regard to the possibility of recurrence: in one case, a young, thin man had a perforation which had existed for a number of hours; the upper abdomen was full of stomach contents and the condition was serious; a closure of the ulcer was done without gastroenterostomy; there was no evidence of stenosis; the patient made a good recovery and reported for a number of weeks in good condition. Six or eight months later the ambulance received a call to a tenement house. The ambulance surgeon found this same young man in bed. He said he had a "perforated duodenal ulcer" and wanted to be taken to the hospital as quickly as possible, as he had recognized his symptoms, and though his condition was good he knew there was no time to be lost. The perforation was nearly in the same place. Dr. Brewer said he closed the perforation and did a gastroenterostomy in the hope that there would be no further recurrence. The man had a few symptoms after that, but he believed that operation prevented recurrence.

Dr. GIBSON said he had a word to add about gastroenterostomy. It might help in the case of another ulcer. Ulcers were sometimes multiple. Unless there was stenosis, gastroenterostomy was hardly justified. He knew a Denver man who had three perforations following gastroenterostomy, so that it could not be considered a safe cure against perforation.

Case of Pituitary Disease with Unusual Eye Symptoms.—Dr. KNAPP presented this case. In this patient, instead of bitemporal or usual homonymous hemianopsia, there was complete blindness in one eye, while the other eye was perfectly normal, not even change in color perception was present. The *x*-ray showed complete obliteration of the sellar fossa with destruction of the clinoid processes. The tumor had evidently broken through the capsule and extended along the right optic nerve. The woman was suffering from headache. That was the only symptom at present. She had had amenorrhea for nine years. There was no particular gain in weight.

Dr. STARR asked what was the carbohydrate test in this case, and if thyroid were being tried.

Dr. THACHER asked if the headaches were severe and if there were any abnormality in the distribution of hair.

Dr. EWING asked what the treatment would be.

Dr. KNAPP said in reply to Dr. STARR that the carbohydrate test had not been done. He had recently learned that less reliance was being placed on this test than before. He wished to get the opinion of the meeting as to the advisability of using thyroid. In reply to Dr. Thacher he said that the patient had lost some hair. In regard to treatment Dr. Knapp said he thought it was important to watch the other eye and if the field in that eye showed involvement, an operation should be considered.

Dr. EWING said that a monograph by Courtellemont, a French alienist, was the most complete presentation of hypophyseal tumors that had yet been published. He first recommended opotherapy; that is, treatment by some of the glands of internal secretion; next, radiotherapy; third, surgery.

Dr. ABBE said that to put in radium tubes through the sphenoid fossa was safe and easy. It had been done in Germany with success.

Dr. STARR said that he had had a case coming to clinic, a boy of fourteen years of age, with tumor of the hypophysis cerebri. He had improved very much on thyroid given in varying doses, running up to a point where he got rapid pulse and lost appetite; in fact, he was kept on the point of being poisoned by thyroid. He had lost the headache and stopped vomiting four months ago. The optic nerves looked very much better than at the start. He had had a partial bilateral heteronymous hemianopsia. The fields of color vision had improved. It seemed as if the boy would make great improvement. He had a very queer shaped head, very large; a slight hemiplegia; a peculiar dryness of the skin; no hair on pubes, and was sexually undeveloped.

Case of Multiple Myelomata.—Dr. THACHER presented an interesting case from the records of the Roosevelt

Hospital. The patient, male, forty-three years, was admitted October 1, 1914, with a diagnosis of nephritis, with some backache. He had had a pain in his back for two months previous to admission, and pain in the back of the chest. When he had lain in bed for a few days the pain disappeared. He was a little tender over the lowest thoracic vertebra and the highest lumbar vertebra. Physical examination showed the knee-jerks markedly increased; slight patellar clonus; marked ankle clonus; no changes in sensation; no Babinski; no Kernig; abdominal reflexes normal; some tenderness to pressure over the lowest ribs; no changes in sensation or pain on touch in that region; there was a slight kyphosis about the junction of the thoracic and lumbar regions. A lumbar puncture was made and there was found a slight cell increase (12 to 14). Noguchi, Butyric acid test strongly positive. Wassermann test twice negative; twice upon spinal fluid positive. He had had a chancroid six years before and was treated by a druggist; no other treatment. It was thought that he had tuberculosis of the spine, but a neurologist said that there was no lesion of the cord and a surgeon said that there was no Pott's disease; a radiologist said that the *x*-ray of the vertebra was normal. The urine was then tested for Bence-Jones protein and it was found abundantly. As this occurred very rarely except in multiple myelomata a search was begun for bone lesions and the *x*-ray pictures were again looked over. It was then thought that lesions could be detected in the ribs. Myelomata occur by preference in the red marrow of thin bones and there appeared to be some slight thickening of the ribs, with an appearance of the ribs being full of bubbles.

At autopsy this was found to be due to invasion. Dr. Leaming said that a place in the angle of the scapula looked as if it were bubbly, but that the underlying lungs might produce that appearance. He thought the appearance in the skull very much more characteristic. He found unevenness in the density of the skull. Finally a lesion was found in the lateral view of the spine. There was a Pott's deformity, not due to tuberculosis. During the patient's stay in hospital the hemoglobin varied very much, according to reports, so that pernicious anemia was thought of, but careful study of the blood did not bear this out. The examination of the blood was often made. Before Bence-Jones protein was found in the urine a blood report was sent in with a differential count of 52 per cent. polys and 46 per cent. lymphocytes; the day after Bence-Jones albumin was discovered, the blood count was altered, and 55 per cent. polys were counted, with 10 per cent. lymphocytes and 32 per cent. plasma cells. The former count should have been similar. After the patient had been in the hospital the pain and tenderness in the back almost disappeared. In one spot of the ribs a spontaneous fracture was later found by *x*-ray. During his stay an extreme salivation occurred with diminution of urine at the time of salivation. He spat out 49 ounces per day at one time, with 10 to 25 ounces urine passed. There was no Bence-Jones albumin in the spinal fluid or in the saliva. The man died on November 26, 1914, of malnutrition and asthenia. At the postmortem examination the bones were found to be very friable.

Dr. Brannan congratulated Dr. Thacher on his very careful study and presentation of the case.

Dr. Ewing said that cases of plasmoma, so called, in the group of myelomata were interesting on account of the difficulty of determining whether one dealt with a true neoplasm or an inflammatory process. In this lesion there was a very wide distribution and the mildly aggressive type was different from the destructive neoplastic type. One wondered whether the milder type developed into the more malignant. He was inclined to think the two types distinct. The cells were most likely different. Some years ago Dr. Norris had shown one extremely malignant case of this type of tumor at the Pathological Society, with many metastases. In the typical myeloma there were supposed to be no metastases, but the literature contained many exceptions so that one could not place much reliance on the presence or absence of metastases. He asked if there were any nucleated red blood cells.

Dr. Thacher said the sections under the microscope showed largely plasma cells and the case had not been sufficiently studied to show any nucleated red blood cells; there were none in the circulating blood.

Senile Paraplegia.—Dr. M. A. Starr read this paper. (See p. 169.)

Dr. Dana said he thought Dr. Starr was right in stating that senile paraplegia had not been adequately studied. Senile paraplegia was only a clinical term and stood for several different things, as Dr. Starr had shown. In the speaker's experience he had met two rather distinct groups of cases. In one there was a flaccid and the other a spastic, or rigid paraplegia. In the flaccid type the patient progressively but intermittently grew weaker in the legs, the muscles wasted, the gait was feeble with short steps and great difficulty in going up and down stairs. There was sometimes lumbar pain. The patients sometimes improved, but eventually became helpless, though the progress was slow. Dr. Dana made an autopsy in one case and found very marked arteriosclerotic changes in the anterior horns of the lumbar region with softening. He thought that in the flaccid senile paraplegias there was always arterial sclerosis of the anterior vessels with softening and at times small hemorrhages. The other type of senile paraplegia was of a rigid character, the patient's legs were stiff; he could not raise the toes from the ground; there was a shuffling gait, suggestive of paralysis agitans. Gowers had described these cases and they were not unfamiliar on the streets. In one case which he had studied there was no change in the reflexes, except diminution with absence of one ankle-jerk. The disease was very slowly progressive, and there were no signs of Parkinson's disease. The spastic type he thought might be explained by supposing a general involvement of the posterolateral as well as the anterior arteries. He had not seen any cases which he thought were neuritic or dystrophic. Such groups as Dr. Starr described might well exist, but histological proof was needed.

Dr. Abbe said he had seen such a case as Dr. Starr had described, of a lady, whom he had watched for five or six years, with a gait becoming more and more shuffling, with paralysis of the feet. Dr. Billings had seen her and had assured him that she was undoubtedly a case of spinal sclerosis, which seemed to him to explain the condition. The process was an ascending one and recently had involved the upper extremities, resulting in paralysis.

Dr. Huddleston said he had seen one case in a man seventy-six years of age corresponding to the first type mentioned by Dr. Starr, that involving the muscles of the legs. The patient presented no spinal symptoms and no neuritic symptoms, but progressive weakness so that at times he could hardly stand on his legs, but there were periods of marked improvement. It would be very interesting, he said, to have an explanation of what was the cause of this curiously varying muscular power.

Dr. Starr said that these three cases he had described were typical of a number of cases that had occurred in the past five or six years. The reason he had brought this matter up was because for the past two or three years he had been accustomed to make a general diagnosis of arteriosclerosis, but cases had accumulated, and in some cases he had been surprised to find that, as Dr. Dana had said, they had improved. If there were degeneration of the spinal cord they could not improve, therefore he came to the conclusion that some of his diagnoses were wrong. Distinctions should be made and a more careful classification established.

He had, therefore, used three entirely distinct cases: (1) myelomalacia; (2) a neuritic type (on account of the changes along the nerves, with anesthesia); (3) muscular type—sufficiently different characteristics to make a distinction between the three cases. Dr. Dana's fourth class, the spastic type, was allied to paralysis agitans. Dr. Starr had never seen these without some manifestation of stiffness and tremors of the hands, or stiffness of the face, characteristic of paralysis agitans, which occurs with or without tremors. This was a well recognized type.

Dr. James said that the apparent assumption that these cases could not be improved because they were arteriosclerosis was not justified, because clinical conditions due to arteriosclerosis elsewhere in the body could be improved.

Dr. Miller asked about the Wassermann reactions; for it would be interesting to know whether luetic infection played any well marked rôle in these cases?

Dr. Starr said that the only case in which a Wassermann had been done had been one simulating locomotor ataxia; this Wassermann was negative.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held December 15, 1914.

DR. JOSEPH C. ROPER, IN THE CHAIR.

Rheumatoid Arthritis.—Dr. BEVERLEY ROBINSON presented this paper. He said that to him rheumatoid arthritis seemed a better name than arthritis deformans, and it was so considered by many who had written most convincingly about this strange affection. It was not rheumatism and it was not gout, but it had the form of rheumatism frequently and the marked deformity of the joints was not apparent always in the beginning of the disease. It had been claimed that rheumatoid arthritis was of infectious origin, but the plausibility of this statement was not supported by facts which were convincing. Notably also the salicylates, which were unquestionably of great value in the treatment of rheumatism, had very little remedial value in rheumatoid arthritis. As to gout, they never found the well marked attacks primarily in the big toe and later the deposits of urate of soda there, in the ears, or elsewhere and, further, the excess of uric acid either in the blood or urine was not found. It was not invariably true that persons suffering from rheumatoid arthritis were run down in health. After describing the symptoms of rheumatoid arthritis, Dr. Robinson emphasized the variability of the symptoms as characteristic of the condition. It was not always the case that a deposit around a joint could be recognized by palpation, and for this reason such joints were often declared to be rheumatic or gouty. Later on the deposits became more pronounced and the cases became the patients of the general surgeons, or orthopedists, and the general practitioner was set aside. Massage, proper mechanical exercises, orthopedic appliances, and rarely operative interference were of service in helping restoration of a function in a measure. To arrest or neutralize the underlying causative factors in the case, we must appeal to a wise and comprehensive judgment of all the efficient elements involved. Overwork, poor food, mental anxiety, frequent confinements, damp, cold, insanitary surroundings, often played a part and a decided one in promoting the development of the disability. On the other hand many cases were found among the well-to-do where none of these factors played a part. At times a lack of exercise seemed to be the cause, and yet when proper exercise was supplied the disease was not arrested. It was true that cutting off much alcoholic stimulant, certain rich wines, and excess of meat had appeared for a while to promote a better state of health, but nevertheless the symptoms returned after a time. The writer concluded that he did just as well with his patients when he placed upon them only limited restrictions as to beverage and food. Some of these patients did very poorly when too much moderation was inculcated. Arbuthnot Lane had claimed that ileocolostomy gave curative effects on the one extreme and Pemberton, at the other, believed he cured these patients by a measured and careful dietary, while the writer did not believe that these extreme laboratory ideas put into practice would endure. In searching for a specific cure for these cases, the author affirmed his belief in the good effects of a dry, warm, bracing atmosphere, woolen underclothes, nutritious, ample, and varied diet, moderate daily exercise in the open air, and a few well-selected drugs if required. Among these the glycerophosphates of lime and soda, cinchona bark with kola, in a palatable tonic wine, were most serviceable. He believed that the benefit derived from the glycerophosphates furnished a clinical reason for the belief that impaired nerve force was directly reponsible for causing not only joint disability, but also the many accompanying symptoms of a general character which were incident to the march of the disease. He felt confident that patients subject to this affection were benefited by a sojourn at Sulphur Springs, Sharon and Richfield, in this country and Aix-les-Bains in France, but he did not advise drinking the water or taking the baths. Such patients must not go to the seashore, nor to the immediate vicinity of the Great Lakes. In the winter they did well in Georgia or South Carolina, or at one of the well known inland resorts. A winter in New York was not favorable to them. Small doses of aspirin internally, massage, dry heat, stimulating liniments, or electricity for the limbs or joints were all helpful. Dr. William Benham Snow claimed that electrical treatment had given an excellent series of cures. But as to any permanently curative effect being produced, that the writer had rarely seen while the patient remained near the seashore, summer or winter. In closing Dr. Robinson quoted from a recent article on this subject as follows: "Laboratory studies alone, although of great value, have very definite limitations; and the importance of considering all practical sides of the situation ought to be perfectly obvious; particularly it seems the many commonplace mistakes which are responsible for a large proportion of failures deserve discussion and prominence occasionally." Many of the new suggestions and new treatments were not a particle better, nor even so good, as what was already known and had stood the test of time.

On the Relation of Blood Sugar to Glycosuria in Diabetes.—Dr. ALBERT A. EPSTEIN said that by means of a serial study (at short intervals) of the blood plasma, it was possible to demonstrate that the blood volume in both normal and diabetic individuals was subject to considerable variations as a result of the ingestion of food and fluids. A serial study of the blood sugar made at the same time, showed that the percentage of sugar in the blood might go up or down as a result of a concentration or dilution of the blood, respectively. That was to say, a decrease in the relative amount of blood plasma (which pointed to a concentration of the blood) could be responsible for the increase in the percentage of blood sugar; and conversely, an increase in the relative amount of blood plasma (pointing to a dilution of the blood) might cause a decrease in the percentage of blood sugar. In order therefore to ascertain the true state of a glycemia or hyperglycemia it was necessary to determine the exact state of dilution or concentration of the blood and to correct the percentage of sugar found by examination, by allowing for the relative concentration or dilution of the blood, *i.e.* the relative increase or decrease in the blood volume. Unless this correction was made, the percentage of sugar found in the blood did not serve as an exact measure of a glycemia or hyperglycemia. Employing this method of calculation in the study of the blood sugar in diabetic patients, a parallelism was found between the hyperglycemia and the glycosuria, provided the renal elimination was in no way impaired. Patients exhibiting evidences of impaired renal function or the presence of renal disease failed to show a definite parallelism between the glycosuria and the hyperglycemia. The lack of parallelism in such cases was naturally due to a lessened permeability of the kidneys for sugar. In cases of diabetes with normal or unimpaired renal elimination, the variation in the daily or hourly elimination of sugar was not due to a unique or haphazard function of the kidneys, but was the result of variations occurring in the true state of the hyperglycemia.

Dr. ARTHUR BOOKMAN said that Dr. Epstein's work and his conclusions had interested him greatly. The most important was the stress laid on the relation of the total quantity of blood to the percentage of blood sugar. The point he made he believed was that in many cases increase or decrease in percentage of blood sugar was only apparent, because if they knew the total quantity of circulating blood they would find that percentage increase in sugar was compensated by a decrease in the total quantity of blood and *vice versa*, so that the *total* amount of blood sugar remained practically stationary. This would be an extremely important point in physiology and demanded therefore careful examination. He said he was familiar with the methods Dr. Epstein had used. Was the information they could give us sufficiently reliable to warrant their acceptance of the conclusions Dr. Epstein had drawn? The method of sugar estimation was that of Benedict, modified by Dr. Epstein for use on samples obtained by finger puncture. He had used this in clinical work and found it convenient for this purpose. It was not, however, absolutely accurate. Because of unavoidable technical variations alone, he believed they must allow for an error averaging probably as high as 10 per cent. even with careful work. Aside from this, picric acid and alkali reacted to other substances besides glucose, whose aggregate in the blood might be important. Another error was introduced by the fact that a single sample of blood might fail to give an average of the blood sugar percentage in the whole circulation. Other observers had found differences in blood from an artery and the corresponding vein. Dr. Bookman had found differences, often large ones, in the blood taken from the finger tip and the arm vein almost simultaneously. Now as to Dr. Epstein's methods of estimating variations in the total quantity of blood. There could be

no doubt that variations did occur, but they were not sufficiently informed as to their extent and causes, because they had no reliable clinical method of determination. Dr. Epstein offers no experimental proof that measuring the space occupied by sediment and fluid in a hematocrite specimen gave them such a method. Quite independent of variations in the blood quantity changes in size and compressibility of the erythrocytes which must occur from chemical and physicochemical changes in the blood, would to some extent influence the length of the plasma column. Local circulatory changes would also influence the proportion of red blood cells and plasma. Professor Stewart had shown that a variety of factors could modify the blood flow in the hands, and that it might even differ in the two hands simultaneously. Furthermore, Dr. Epstein had told them nothing as to the relation of the plasma volume of the blood he used for his determinations to the average in the circulation elsewhere. Unless this be constant his method could not yield reliable data even as to the proportion of cells and plasma alone. It was difficult therefore to agree with Dr. Epstein that he had given them a satisfactory measure of the total quantity of blood. Attractive as his conclusions were, therefore, they seemed to require further proof. Until this was brought it would remain probable that variations in the percentage of sugar did really mean as a rule variations in the total quantity of blood sugar.

The following were contributions by the medical staff of Lincoln Hospital:

Auricular Fibrillation with Unusual Response to Strophantin.—Dr. ALBERT VANDER VEER reported this case. The patient was a woman, married, 29 years old. She had smallpox when a child, rheumatism at ten years with recurrent attacks every few years since then. For the past three years she had had attacks of palpitation of the heart and dyspnea. For three months had had dull pain in the epigastric region and for several weeks dyspnea and pain over the liver. She was admitted to Lincoln Hospital, Nov. 15, 1914. The physical examination showed a patient poorly nourished, cyanotic with extreme dyspnea and marked venous pulsation in the neck. There was impulse heaving over the entire precordium with a thrill at the apex whose time could not be definitely determined. The heart was enlarged about one-half inch to the right of the sternum and six inches to the left with apex in the sixth interspace. On auscultation the heart was rapid and irregular with a systolic murmur at the apex and several other murmurs whose time could not be definitely determined. Heart was beating about 176, pulse 66 and very irregular, giving a pulse deficiency of 110. There was no fluid in the chests and no edema. The liver was enlarged 2 inches below the costal margin and not pulsating. After one day's rest in bed the heart was 135, pulse 72, deficiency 63. Patient was then given .001 gm. strophanthin intravenously. In five minutes, heart 107, pulse 60; ten minutes, heart 87, pulse 71; fifteen minutes, heart 84, pulse 83; thirty minutes, heart 78, pulse 75.

The patient was relieved of her dyspnea in five or ten minutes. Next morning (Nov. 17) heart 45, pulse 45; afternoon heart 41, pulse 41. Patient was comfortable. Nov. 18, heart 62, pulse 58. Put on one digipuratum tablet each night.

For about a week the heart stayed around 59, pulse 57. Patient was then up and around the ward, heart about 70, pulse 64. She was transferred to the surgical division and an epulis removed from the lower jaw. She was discharged from the hospital several days later, heart 76, pulse 69. On discharge from the hospital the examination of the heart showed, apex in the sixth space about five and one-half inches from the mid line, right border at right border of the sternum. A faint presystolic thrill and murmur inside apex, marked diastolic thrill at apex, with loud systolic and diastolic murmurs heard best at the apex but also at the base and along the left side of the sternum.

Pernicious Anemia.—Dr. VANDER VEER reported this case.—The patient was a male, married, and gave no history of tuberculosis or malignancy. Nothing of importance in his previous history until 1907 when he had a fracture of the thigh from which he recovered with no disability. He was a moderate drinker. Five weeks before admission to the hospital he was hit in the side by a piece of flooring. The blow was not a hard one as it did not break a pair of glasses carried in his pocket. Until this time he had felt perfectly well but after a few days he began to have dyspnea and the pain in the side bothered him considerably. In five weeks he lost about twenty pounds, felt very weak and noticed that he was becoming pale. On admission to the hospital, June 15, 1914, the physical examination showed a man well nourished but very pale, weight 170 lbs., teeth in fair condition, pupils equal and reacting, heart enlarged about an inch to the left, faint systolic murmur at the apex, lungs negative, liver and spleen not enlarged, marked tenderness over ninth and tenth ribs below left nipple, no fracture made out, knee jerks normal and no ataxia. Blood examination: hemoglobin 25 per cent., red blood cells, 1,890,000; color index 0.7. Four normoblasts with slight changes in the shape and size of the red cells. White blood cells, 9,600; differential, polymorphonuclears 60 per cent., small lymphocytes, 36 per cent., large lymphocytes, 2 per cent., eosinophiles 1 per cent. Three urine examinations were negative. Examination of the feces showed no blood and no parasites. Sputum was negative for tubercle bacilli; Wassermann negative; no malarial parasites. *X*-ray examination of the chest was negative except for enlargement of the heart to the left. Test meal, free HCl 60, no lactic acid, no blood. A tentative diagnosis of pernicious anemia was made. The patient ran a slight temperature up to 100.5° for ten days when it became normal. Was given red bone marrow 5i four times a day and rectal irrigations; later he was given digipuratum tablets and iron and arsenic. He constantly complained of pain in the left chest and occasionally expectorated a little blood. With this pain in the chest he sometimes had attacks of vomiting and dyspnea. Blood counts, June 20, hemoglobin, 32 per cent.; red cells 1,400,000; color index 1.14. June 27, hemoglobin 32 per cent.; red blood corpuscles, 2,400,000; color index .7. July 10, hemoglobin 35 per cent.; red blood corpuscles 1,800,000; color index 1. White cells always about 7,000, with a normal differential. The patient was discharged July 23, 1914, improved. Weight 166 lbs. He felt pretty well until August 12, when he had more pain in the side, and dyspnea, and went to Sydenham hospital. On admission here his blood count showed hemoglobin 50 per cent.; red blood corpuscles 1,500,000; color index 1.7; white blood corpuscles 6,000, differential normal. The physical examination was negative except for the anemia. The *x*-ray was negative. Sputum negative except for some red blood cells. Urine on four examinations showed many red blood cells. He was discharged improved after several weeks' stay. He was fairly well until October when he again came to Lincoln hospital and was admitted October 29 in very poor condition requiring stimulation. He was given strophanthin gm. .001 intravenously without any effect on his pulse. Blood at this time showed hemoglobin 34 per cent.; red blood corpuscles 850,000; color index 2, with marked poikilocytosis. One week later hemoglobin 24 per cent.; red blood corpuscles 560,000; color index 2. He was in pretty poor shape all this time, drowsy, much dyspnea and pain in the side, occasional attacks of vomiting. Physical examination was same as before. *X*-ray, Wassermann and stools were all negative. Gums negative for amebæ. Sputum negative for tubercle bacilli, but showed a small amount of blood. Urine at one time showed a few red blood cells. Test meal, no free HCl, no blood, lactic acid present. Tension, systolic 128, diastolic 64. He received mixed treatment and rectal irrigations, later sodium cacodylate hypodermically. He grew steadily worse, refused to eat, refused his irrigations, and ran a slight temperature all the time. Complained of dimness of vision and eye examination on Nov. 9 showed small retinal hemorrhages. Was kept out of doors all the time. Nov. 20 was put on large doses of lactic acid bacilli. Soon after this his appetite improved, the pain in his side let up, and he felt better. Nov. 27 blood count showed hemoglobin 28 per cent.; red blood corpuscles 840,000; color index 1.7. Dec. 2 hemoglobin 40 per cent.; red blood corpuscles 1,760,000; color index 1.14; no nucleated reds. Continued to improve and on Dec. 3 was allowed up for a time. Dec. 12 hemoglobin 57 per cent.; red blood corpuscles 2,680,000; color index 1.06. He was now up and around the ward and apparently was in his third remission. Weight 158 lbs. Tension systolic, 120, diastolic 56. No ataxia, knee jerks all right. Eyesight had not improved. Test meal showed total acid 14, no free HCl, lactic acid a trace.

An Unusual Case Presenting Features of Addison's Disease.—Dr. CHARLES E. S. WEBSTER reported this case. The patient was admitted to the medical service of Dr. Barrett on April 19, 1914. She was a housewife, 30 years of age. The history obtained was meagre. Her father died of apoplexy. The rest of her family

were alive and well. Except for an attack of measles when a child she had had no other illness until the present. She was married at the age of 23, had had no children and no miscarriages. Her present illness began six months ago with "failing health;" she noticed that she was getting thin, her appetite was poor, and she had tingling pains in her legs. Neither the patient nor her relatives knew the exact time when she began to grow darker in color. She was treated by a physician who diagnosed her case as neuritis. On admission to the hospital the physical examination showed a very marked emaciation, with abrasions on the elbows and with the entire skin being very delicate. She had a brownish discoloration of the skin, most marked in exposed areas, but not uniform. The pupils were regular, reacted to light and accommodation, and there was no strabismus or nystagmus. The roof of the mouth showed a few brownish, discrete and discolored areas of a grayish brown color. The abdominal organs were apparently normal. The extremities showed the most marked emaciation, especially the hands which seemed almost transparent. Her reflexes were exaggerated. There was no Kernig's sign and ankle clonus was elicited with difficulty. Her speech was slow and mentally she was very dull. If undisturbed the patient was never still. She would talk, laugh, sing or cry, and move about aimlessly in bed; but the skin was abraded and she had to be restrained. If questioned she would not respond. She had no delusions and no hallucinations. She was not conscious of her apparent dementia. Gradually her asthenia increased. It became more and more difficult to feed her. She at last fell into a semi-coma which deepened to coma three days before her death. Her temperature varied. The blood examination showed 4,300,000 red cells, 9,600 white cells, polymorphonuclears 64 per cent., lymphocytes 28 per cent., eosinophiles 2 per cent. The Wassermann reaction was negative. The diagnosis of Addison's disease was made without much hesitation, but there were several features in the case which seemed to demand some explanation. This was furnished by Dr. Rohdenburg who performed the autopsy. The subject was that of a sparse, emaciated female, about 45 years of age, weighing about 110 pounds. There was a moderate amount of discoloration in her flanks and about the back. There were no visible scars. The color was pale brown. The microscopical examination of the pulmonary apices showed no evidences of tuberculosis. The patient had chronic interstitial nephritis. The chief lesion of interest was that found in the adrenals. Both the right and left were found to be enlarged about twice their normal size prior to section, and studded just beneath the gland capsule with numerous small millet seed like granules. On microscopical examination these masses proved to be typical tubercles with giant cells, numerous lymphocytes and by special stains tubercle bacilli were demonstrable. Just over the Sylvian fissure there was an opaque mass beneath the meninges which was found to be attached locally by a few delicate fibrils to the meninges, the main mass being in the brain substance proper. This measured 1 x 1¼ inches and was located in the posterior temporal convolution. On section it was found to be cream colored and sharply demarcated from the surrounding normal brain tissue. The microscopical examination showed the presence of typical tubercles; no tubercles were found in the overlying brain coverings. The anatomical diagnosis was made of tuberculosis of the adrenal glands, tuberculosis of the brain, and chronic interstitial nephritis.

Report of a Case of Osteitis Deformans.—Dr. HENRY C. THACHER reported this case and gave a lantern slide demonstration. The patient was a colored woman, 60 years old, with mild "rheumatism" of three or four years' duration; this involved the cranium, the vertebræ, the pelvis, the femur, and the tibia. Of particular note were (*a*) the abrupt involvement of the upper third of the left tibia with normal bone below and (*b*) the dense, ivory-like osteosclerosis of the femora in striking contrast to the large soft irregularly calcified bone in cranium and tibia. The latter gave *x*-ray plates strikingly similar to pictures of lues. They frequently found extreme arteriosclerosis was present. The Wassermann reaction was negative.

Some Recent Work on Cardiovascular Disease.—Dr. LOUIS F. BISHOP presented this communication. (See page 173.)

Election of Officers.—*Chairman*, Dr. T. Stuart Hart; *Secretary*, Dr. Nellis B. Foster.

State Medical Licensing Boards.

STATE BOARD OF EXAMINATION QUESTIONS.

NEW YORK STATE BOARD OF MEDICAL EXAMINERS.

May, 1914.

(*Continued from page* 126.)

OBSTETRICS AND GYNECOLOGY.

Answer a total of 10 of the questions on this paper but no more.

Candidates must answer each of the first six questions.

1. Give the mechanism of labor in the right occipito-posterior presentation.
2. What is meant by (*a*) internal podalic version, (*b*) bipolar version?
3. What is the preventive treatment of post partum hemorrhage?
4. How would you guard against injury to the soft parts in the second stage of labor?
5. What care should be given the patient during the immediate puerperium?
6. Describe the obstetric forceps and give the indications for their use.
7. Give the technique of vaginal cesarean section.
8. What is meant by Bandl's (constricting) rings?
9. Give the mechanism of labor in the left occipito-posterior presentation.
10. Define version. Give the management of breech extraction.
11. Describe the manner of using the forceps in delivery.
12. What conditions that may occur during pregnancy are due to toxemia?

PATHOLOGY.

Candidates must answer questions 1, 2, and 3.

1. Describe a method of preparing a portion of a tumor for making sections for microscopic examination.
2. Describe the gross anatomy of the lung in the various stages in lobar (croupous) pneumonia.
3. What is meant by serum sickness or anaphylaxis?

Candidates must answer two of the following questions, but no more.

4. Describe the blood in lymphatic leucemia.
5. Differentiate the varieties of pneumonia.
6. What diseases are associated with a change in the thyroid secretion?

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. *Mechanism of R. O. P. Position.* "1. Flexion. 2. Descent, as in anterior position of the occiput. 3. Rotation. In the large majority of cases (96 per cent.) the occiput rotates all the way round to the symphysis pubis. In doing so it passes the right acetabulum, but it no sooner reaches this point than it becomes practically and in reality a right anterior position, and the rest of the mechanism is precisely the same as that for the R. O. A. position. In the small minority of cases (4 per cent.) the occiput, instead of rotating forward, rotates backward to the sacrum, and the forehead comes to the pubes. Then follows, 4, extension, which takes place, not upward toward the mons Veneris, but the occiput escapes over the perineum, and is depressed outside of it downward and backward toward the anus, while forehead, nose, mouth, and chin, successively emerge under the pubic arch. 5. Restitution. By internal rotation of the shoulders, one goes to pubes, the other to sacrum, and the occiput rolls around to the right thigh (the thigh corresponding to the sacroiliac synchondrosis at which it orginally presented."—(King's *Manual of Obstetrics.*)

2. *Internal podalic version* is that form of podalic version in which one hand is introduced into the uterine cavity.

Bipolar version is that form of cephalic version in which the position of the fetus is altered by pressure on both poles of the fetal ellipse, one hand of the obstetrician being placed on the abdominal surface of the mother, and the other in the vagina.

3. *Preventive treatment of postpartum hemorrhage.* "This must be addressed to the uterine retraction. The uterus should be watched, with the hand continuously on the abdomen, from the birth of the child and for at

least a half hour after the placenta is delivered. Care should be taken that no fragment of placenta is left in the uterus. Friction may be used if required to provoke normal contractions. Too early resort to Credé's manipulation may cause imperfect separation of the placenta, and produce hemorrhage from partial separation of the placenta. In persistent inertia, ergotole 5ss, and pituitrin (1-3 decigrams) injected hypodermically, and repeated, p. r. n., is a valuable prophylactic. It is often indicated after chloroform anesthesia, and in all conditions which predispose to hemorrhage. It is a wise precaution to give ergot on birth of the head when there is reason to fear postpartum hemorrhage. It is the abuse, not the proper use, of ergot that has brought it into disrepute in certain quarters."—(Polak's *Manual of Obstetrics.*)

4. *To protect the perineum:* The patient should be restrained from bearing down unduly; extension of the head must be retarded, and the central part of the occiput must be allowed to be born first; pressure must be made with the hand between the coccyx and the anus; when the perineum has had time to stretch, extension and expulsion are allowed; after the birth of the head care must be taken to see that the perineum is not torn by the birth of the shoulders.

5. *Care of mother during puerperium:* "*During the first week* the patient keeps the bed, but after the first few hours she has considerable license. She may assume the sitting or half-sitting posture to take her meals and to nurse the baby, and, if necessary, for evacuation of the bladder and rectum. She should assume the lateroprone posture both right and left, several times a day, and lie upon her abdomen for at least an hour daily. Frequent change of position favors uterine drainage and massages the uterine supports. *During the second week* she has greater liberty, while the greater part of her time is spent on the bed or lounge. She may sit up for her meals, to urinate, and for bowel movements, and she should spend at least half an hour, twice daily, in abdominal and leg exercises to keep up her muscular tone. *The third week* she may be moved to a chair for a part of the day, having the liberty of the room. After sitting up for any length of time she should be instructed to take the genupectoral position before lying down. Prescribed exercises for the legs and abdominal muscles are to be taken daily. *The fourth week*, if all goes well, she may leave the room and have the benefits of air and sun. Physical exercises should be continued. The duration of the lying-in period and the degree of freedom to be given the patient after the second week must, however, depend on the character and amount of the lochia, the general progress of her convalescence, and the rate of the uterine involution."—(Polak's *Obstetrics.*)

6. "*The obstetric forceps* is an instrument devised for grasping the fetal head in difficut labor and by traction aiding its exit. There are two varieties—namely, the simple, including the short and the long, and the axis-traction forceps. A *short* forceps is one in which the blades of the instrument are attached directly to the handles without the intervention of a shank; it possesses the cranial or cephalic curve only—that is, the outward bulging of the blades by which its accurate adaptation to the fetal head may be accomplished; this curve should be the arc of a circle, the radius of which is about 4½ inches. The *long* forceps is one in which a shank is placed between the handles and the blades for the purpose of adding length to the instrument. It has, in addition to the cephalic the pelvic curve, or upward turning of the blade, corresponding to the curve of the parturient canal. By an *axis-traction* forceps is meant a variety of long obstetric forceps in which, by an appliance or supplementary handle attached to the under surface of the blades, the traction-force is exerted in the line of the axis of the parturient canal, and, therefore, rendered more effective, while at the same time it is reduced to a minimum. Traction is effected entirely by the supplementary and not by the primary handles."—(Dorland's *Obstetrics.*)

Indications for the use of forceps are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A. Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 3. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."—(From Jewett's *Practice of Obstetrics.*)

7. *Vaginal cesarean section:* "An intramuscular injection of ergot may be given shortly before operation. In primiparæ room is obtained by a right lateral vaginoperineal incision. The field is exposed by retractors. The cervix is drawn well forward with two traction forceps, one caught in each lateral aspect of the anterior lip. The anterior vaginal wall is incised longitudinally from a little behind the urethra to the anterior lip of the cervix. The bladder is detached from the uterus as in vaginal hysterectomy. If required, the anterior vaginal wall may be separated from the bladder. The bladder is held up with a suitable retractor passed beneath the pubic arch. The anterior uterine wall is split in a sagittal direction from the lower border of the cervix to a point above the internal os, a distance of about 6 to 10 cm. The single anterior incision affords sufficient space for the extraction of the child up to the eighth month. A posterior uterine incision also is required in full term deliveries. The amniotic sac at once protrudes. Membranes are ruptured and child extracted, generally by version, or, when the head is fixed or can be engaged, by forceps. The placenta is removed and the uterus firmly packed with gauze until the sutures are placed. The uterine incisions are closed with sutures. The vaginal and perineal incisions are sutured, a drain of gauze or rubber tissue being left between cervix and bladder. The drain is removed in 24 hours.—(Polak's *Obstetrics.*)

8. *Bandl's constricting ring* is a line of demarcation between the thickened upper uterine segment and the thinned lower uterine segment; it is developed during the first stage of labor, and is clearly defined during a pain.

9. *Mechanism of L. O. P. position.* 1. Flexion. 2. Descent. 3. Rotation, in the majority of cases all the way round to the symphysis pubis (when, on reaching left acetabulum, it, of course, becomes converted into a L. O. A. position); in the minority of cases backward rotation of occiput to sacrum. 4. Extension of occiput downward and backward over perineum, while forehead, nose, and chin, successively escape under pubic arch. 5. Restitution, internally of shoulders, right one to pubes, left to coccyx; externally of occiput to left thigh (thigh corresponding to the sacroiliac synchondrosis at which it originally presented).—(King's *Obstetrics.*)

10. *Version* is a maneuver by which some part of the fetus other than that originally presenting is brought down to the superior strait of the pelvis.

BREECH EXTRACTION: "*First stage.*—Keep the patient in bed and at rest, so as to preserve the membranes as long as possible. Warn the relatives of the risk to the child. *Second stage.*—Prepare warm towels to wrap around the child's body and limbs, and a warm bath, and everything likely to be required for the treatment of asphyxia. Allow the breech to be born without hurrying it. Support the perineum as in a vertex case. As soon as the body is born as far as the umbilicus, draw down a loop of the cord, at the same time maneuvering it to the corner of the pelvis, where it is least likely to be compressed. This loop by its pulsations is an index of how it is faring with the child. Wrap the limbs and trunk in a warm towel, and hold them slightly towards the mother's abdomen so as to aid the lateral flexion of the body. At the same time exert suprapubic pressure upon the fundus, which aids expulsion and promotes flexion. When the elbows appear the hands may be gently disengaged with the finger. Meantime carefully watch the pulsations of the cord. Provided it is beating regularly and the child is not making convulsive movements, there is no need for anxiety. Wait for the next pain and with the aid of suprapubic pressure expel the head in a fully flexed attitude. *Extraction of the head.*—If the head be delayed more than a few minutes after the birth of the trunk as far as the umbilicus, it will almost certainly require to be artificially aided. The two best methods of doing this are (1) the Prague seizure, and (2) the Mauriceau-Smellie-Veit grip. Both are designed to extract while at the same time promoting flexion. Therefore aid the latter by making the nurse or assistant exert suprapubic pressure while the extraction is being performed. Either method is more easily performed if the mother is in the cross-bed position on her back. This position can only be maintained by the aid of assistants, but if such aid is available it

is often desirable to place the mother in this position as soon as the breech reaches the vulva. Anesthesia is also required. *Prague seizure.*—Seize the feet and legs by one hand and carry them well forward between the mother's thighs. Place the first and second fingers of the other hand over the child's shoulders to steady the head. Pull upon the legs in a direction at right angles to the mother's abdomen. This forces the occiput against the pubes and so increases flexion, while it also effects extraction, which is controlled by the fingers over the shoulders. In a primipara this method may require such force that the head comes out with a suddenness that causes severe tearing of the perineum. In these cases the second method is perhaps better. *Mauriceau-Smellie-Veit Grip.*—Place the child astride upon the left forearm, and slip the two first fingers of the left hand into the vagina and apply them to the superior maxilla on each side of the nose. With these fingers try to draw down the chin and nose, and so promote flexion. At the same time the two first fingers of the right hand are passed over the shoulders and traction made by them in an upward direction. An alternative is to pass the left forefinger into the mouth, but this is apt to cause injury to the jaw.—(Johnstone's *Midwifery.*)

11. *Manner of using forceps:* "They should not be used when the os is undilated, when the head is not engaged, except in placenta prævia, when the membranes are unruptured, when the disproportion between the child's head and the parturient canal is too great, or in impossible positions and presentations. Before applying the instruments they should be sterilized, preferably by boiling; and the patient anesthetized and placed in the lithotomy position. Two fingers of the right hand are introduced into the vagina; the left blade of the forceps is then held almost perpendicularly by the left hand, with the tip of the blade opposite the vulva; the tip is introduced into the vagina, passed along the floor toward the sacrum. The blade is rotated outward in its long axis in order to escape the promontory of the sacrum. The right blade is introduced in a similar manner. To facilitate locking, one of the blades must be rotated forward. If the head occupies the right oblique diameter, as in L. O. A. and R. O. P. positions, the right blade must be rotated; if it occupies the left oblique diameter, the left blade must be rotated. Traction is made in the direction of the pelvic axis until the perineum is well distended. The perineum is then protected by one hand, while the face is swept over it by an upward movement of the forceps. In posterior positions it is necessary to remove the instruments after the head is drawn down to the pelvic floor; after anterior rotation is secured they may be reapplied. If the occiput rotates into the hollow of the sacrum the hands should be depressed as the face is swept out under the symphysis pubis."—(*Pocket Cyclopedia.*)

12. "The important signs and symptoms of the toxemia of early pregnancy are those indicated by disturbances in digestion and assimilation, an altered state of the blood, and as a result nausea and vomiting, persisting throughout the patient's waking hours. Accompanying this is great prostration, loss of appetite, a heavy lethargic sleep, later giving place to unpleasant dreams and restlessness, the failure to retain anything upon the stomach, obstinate constipation, and substernal pain extending from the epigastrium. The pulse is rapid and grows progressively weak, respiration is sluggish, and as the disease progresses the matter ejected from the bowel contains an abundance of disintegrated blood cells which resemble coffee-grounds. The urine is diminished greatly in quantity, with high specific gravity, frequently albuminous, and often contains epithelial or granular casts. The nitrogen partition shows greatly lessened urea with corresponding increase in creatin and creatinin, the rest nitrogen is increased, and indican is present. Casts of various sorts are often found. As the disease progresses the patient in some cases becomes greatly emaciated, in others there is considerable deposit of fat, the action of the heart is progressively rapid and weak, frequently becoming thready and irregular. The mouth and gums become covered with sordes, the odor about the patient is offensive, and the skin is in places the site of a purpuric or hemorrhagic condition." (Davis's *Manual of Obstetrics.*) Later on eclampsia may ensue.

PATHOLOGY.

1. "Place in 95 per cent. or absolute alcohol for 24 hours; then in ether and 95 per cent. or absolute alcohol (equal parts) for 24 hours; then in thin celloidin for from 24 hours to 1 or more weeks; then in thick celloidin for from 24 hours to 1 or more weeks; then mount on blocks of vulcanized fiber; dry for 1 or 2 minutes in the air; then harden the celloidin in 80 per cent. alcohol for from 6 to 24 hours." (*Cyclopedia of Medicine and Surgery.*)

2. ACUTE LOBAR PNEUMONIA. "It is convenient to describe four stages, those, namely, of (1) hyperemia or engorgement, (2) red hepatization, (3) gray hepatization, and (4) resolution. *First stage or splenization.*—The lung is injected, dark red, and heavy, and pits under the finger; on pressure, there exudes a frothy serum tinged with blood and slightly aërated. The lung still floats in water. *Second stage or red hepatization.*—The part involved is solid and friable, presents a granular or red granite appearance, and sinks in water. The alveoli are filled with a coagulated exudation, which shows under the microscope fibrin, leucocytes, red corpuscles, proliferated alveolar epithelium, and pneumococci. *Third stage or gray hepatization.*—The lobe has now the appearance of gray granite, the lung substance is softer and more friable; on pressure, a dirty purulent fluid exudes. The gray appearance is due to four factors: (1) Decolorization of the red blood corpuscles; (2) obliteration of the alveolar blood vessels from pressure; (3) fatty degeneration of the coagulated material; (4) great infiltration of leucocytes. A more advanced stage, in which the lung tissue is bathed in purulent fluid, is known as purulent infiltration. It is probably inconsistent with life. *Fourth stage or resolution.*—Resolution of the inflammatory exudation is brought about principally by absorption (autolysis), but partly by liquefaction and expectoration. Pneumonia may affect a lobe, or the whole of a lung, or it may attack both lungs. Double pneumonia occurs in about 10 per cent. of cases. Different parts of the same lung may at the same time show different stages. There is always some degree of pleural inflammation over the affected area. Modern enlargement of the spleen is very common." (Wheeler and Jack's *Handbook of Medicine.*)

3. *Serum sickness* is the name given to a series of symptoms (fever, skin, eruption, swollen joints, edema, enlargement of glands) occurring about eight or ten days after the injection of a serum.

4. In *lymphatic leucemia* the blood shows a decided leucocytosis, about 90 per cent. being lymphocytes, the proportion of polynuclears is much reduced; there are no myelocytes, and there may be a few nucleated red corpuscles; the red cells may be slightly diminished, the hemoglobin is diminished.

5. For *lobar pneumonia*, see QUESTION 2.

Bronchopneumonia: "The disease affects both lungs, and begins in the terminal bronchioles, spreading thence to the infundibula and alveoli. The consolidated patches have therefore a lobular arrangement, but if many adjacent lobules are affected the consolidation may be almost lobar. The bronchioles are inflamed and frequently plugged with mucus, and their walls and the surrounding interstitial tissue are infiltrated with small cells. The walls of the air vesicles in the consolidated area are congested, their epithelium is swollen, and their lumen is filled with proliferated epithelial cells, leucocytes, and a mucous or mucopurulent (not fibrinous) exudate. Many lobules are collapsed, but not inflamed, from plugging of the bronchioles. When cut into, the small consolidated areas are seen to be conical in shape, with their bases towards the pleura, reddish in color, with indefinite margins, and separated from each other by crepitant lung tissue. Adjacent lobules may be emphysematous (compensatory emphysema). The bluish-gray collapsed areas are most numerous in the lower lobes."—(Wheeler and Jack.)

Chronic interstitial pneumonia. "The overgrowth of interstitial connective tissue produces the following changes: 1. Encroachment upon and subsequent obliteration of the air vesicles. 2. Changes in the bronchial tubes, their muscular coats being replaced by fibrous tissue. The tubes subsequently yield to intrapulmonary traction, and form bronchiectatic cavities. 3. Obliterative changes in the smaller pulmonary and bronchial blood-vessels. The lung as a whole is shrunken, often enormously, airless, and hard. The opposite lung is emphysematous, and the right ventricle is hypertrophied."—(Wheeler and Jack's *Handbook of Medicine.*)

6. Absence of thyroid secretion causes cretinism; *diminution* of it causes myxedema; *increase* of it causes exophthalmic goiter.

(To be concluded.)

FURTHER OBSERVATIONS ON THE TREATMENT OF SCIATICA BY PERINEURAL INFILTRATION WITH PHYSIOLOGICAL SALINE SOLUTION.*

By WILLIAM M. LESZYNSKY, M.D.,

NEW YORK.

ATTENDING NEUROLOGIST AT THE LEBANON HOSPITAL; CONSULTING NEUROLOGIST TO THE HARLEM HOSPITAL; AND CHRIST HOSPITAL, JERSEY CITY.

In a paper published in the New York Medical Record of February 17, 1912, I reported twenty-five cases of sciatica treated by perineural infiltration with physiological saline solution. Since that time I have adopted this procedure in one hundred and thirty-five additional cases. The number of injections required for the individual case varied from one to six, but averaged three injections for each patient. Thus, about four hundred and eighty injections have been given in one hundred and sixty cases.

Complications or unpleasant symptoms have never been encountered. Under proper technique and strict asepsis it is a harmless operation. As a result of this larger experience, I must reiterate the statement made nearly three years ago, that "perineural infiltration of normal saline solution at the sciatic nerve, when properly performed, proves a valuable acquisition in relieving the pain of sciatica whether acute or chronic."

Several patients have not reacted satisfactorily, or have not given the plan an adequate trial, but they have been the exceptions. From one to six injections are required to secure permanent relief. In numerous instances one or two injections have sufficed. I do not recommend this treatment in every case, for many patients are often relieved and recover under the customary therapeutic procedures. In subacute and chronic intractable cases, however, it has proved, in my experience, the most satisfactory addition to our therapeutic armamentarium that has yet been devised. While this method has been cursorily mentioned by several writers within the last few years, it has not received the recognition that its importance demands. Constitutional treatment must not be neglected, and after relief is obtained from the injections it is often necessary to utilize supplementary measures in order to prevent a recurrence.

It is not my intention to enter upon a general discussion of the subject of sciatica. Many of us have long been familiar with the fact that the diagnosis of "sciatica" is often carelessly made from the patient's statement as to the location of the pain, and without the necessary physical examination. Rectal and pelvic investigation are essential in every case. A common source of error is the failure to recognize the presence of hip-joint or pelvic disease, or involvement of the sacroiliac joint. In some instances the possibility of spinal cord tumor should be considered. In over 75 per cent. of the cases sciatic perineuritis was assumed to exist, as the characteristic symptoms were present in varying degree, *i.e.* pain and tenderness at the sciatic notch and over the nerve trunk, pain on extension of the leg with the thigh at a right angle with the abdomen, and diminution or loss of the Achilles reflex. This type of sciatica seems to be most amenable, and reacts more rapidly and satisfactorily to this mode of treatment. In the case of a young woman with severe pain and paralysis in the sciatic distribution of five weeks' duration, due to pressure from a large pelvic abscess, one injection produced relief for twenty-four hours. The patient stated that it was the first night of freedom from pain that she had experienced in several weeks. It is hardly necessary to mention that suitable surgical measures were promptly instituted.

In reply to numerous inquiries, and for the information of those unfamiliar with the subject, extracts from my previous paper with a description of the technique will be in order.

This method was first brought to the attention of the medical profession in 1907 by Dr. J. Lange of Leipsic in an article read before the Congress for Internal Medicine held at Wiesbaden. The procedure consists in the injection of a large quantity of fluid under pressure directly over the sciatic nerve. Lange claimed that the favorable results obtained were entirely due to the mechanical action of the fluid in loosening, stretching, or breaking up adhesions in the neighborhood of the nerve. But, in view of the fact that I have repeatedly produced prompt and permanent relief from pain in acute or very recent cases, such favorable results must have been due either to blocking of sensory conductivity, or to the pressure and absorption of the fluid producing changes in the circulation and nutrition of the perineural structures. In acute cases it would be too early to assume the presence of adhesions. Lange originally used a solution containing beta-eucaine, but I have found it unnecessary, as the saline solution alone proves adequate and in every way satisfactory.

The technique is as follows: During the application of the treatment the patient should lie on the abdomen with the legs fully extended, and the feet projecting beyond the edge of the table. A firm pillow is rolled and placed under the lower part of the abdomen in order to favor relaxation of the gluteal muscles. For the purpose of locating the nerve the following measurements are made: A line is drawn from the sacrococcygeal articulation to the postero-external border of the great

*Read at a meeting of the Medical Society of the County of New York, December 28, 1914.

trochanter; at the junction of the inner one-third and the outer two-thirds of this line is found the spine of the ischium. One inch to the outer side of this point we locate the point of puncture. An area of the skin about 4 cm. in diameter is then painted with iodine, the point of puncture being in the center. The syringe used is all metal, holding 60 c.c. (2 ounces). It has a slip tip which allows the needle to fit the barrel directly. The needle is of steel, 12 cm. long, with a caliber of 2 mm., and provided with a sharp point, which is protected by a dull-tipped stylet projecting 1 mm. beyond the point of the needle. In puncturing the skin and subcutaneous tissue, the stylet is withdrawn beyond the cutting edge. It is then replaced, and the needle pushed in perpendicularly. When the sciatic nerve is reached, at a depth ranging from 6 to 12 cm., the patient may feel either a sharp pain radiating from the point of contact to the popliteal space or down to the foot; or, a sharp pain in the corresponding heel; or, there may occur a jerking movement of the leg; or, a sudden twitch in the calf muscles. Some patients complain only of diffuse pain in the buttock. The stylet is then removed. The syringe having been filled with sterile physiological saline solution at a temperature between 95° and 100° F., the fluid is rapidly injected. The quantity used is from 80 to 120 c.c. The needle is then quickly withdrawn, the iodine washed off with alcohol, some collodion applied over the point of puncture, and this is covered with a small strip of sterile adhesive plaster. The patient is then instructed to lie abed and rest for twelve to twenty-four hours. No anesthetic is required. Strict aseptic precautions are absolutely essential. Soon after the injection, some aching pain with a sensation of heaviness and numbness in the limb usually follows, but this lasts only a short time. In some cases the sciatic pain in the thigh disappears within twenty-four hours, but the patient complains of pain continuing in the leg in the course of the peroneal nerve. This is often promptly relieved by an injection of 15 to 30 cc. in the region of the nerve at the head of the fibula. The interval following the first injection, before another is given, will vary according to the degree of relief obtained. I have been in the habit of waiting from thirty-six hours to one week before repeating the injection.

As a rule, the injection of saline solution under pressure, in quantities ranging from 60 to 120 c.c. or more, is attended with comparatively slight pain. This usually arises during the early period of the injection. As soon as heaviness and numbness in the extremity are felt, no further pain results from the introduction of additional fluid. In the majority of instances the treatment is not painful. At the time of the first injection fear and apprehension often render some patients less manageable than others. Usually, when additional injections are required, these elements of discomfort have become eliminated, and there is no further difficulty. It should be borne in mind that our object is to produce infiltration of the nerve and the surrounding structures. It is not intended that the nerve sheath should be entered by the needle. Should such a large quantity of fluid be forced into the trunk of the nerve disagreeable consequences, such as paralysis and traumatic neuritis, would probably ensue. In the construction and use of the special needle precautions are taken to avoid puncturing a blood vessel or the nerve sheath.

Case I.—My first case treated by this method in March 1911, presented a striking illustration of its beneficial effect. The patient was a man forty years of age who had suffered from sciatica for one year. Many drugs and external applications had been unsuccessfully utilized at the various clinics and at home. He had been in the general medical service of the hospital for six weeks without improvement, during which time he had been confined to bed, unable to move without great pain. Immediately after one injection, he walked from the operating room back to his bed, a distance of one hundred feet. The relief from pain was prompt, improvement in his general condition was rapid, and in the course of ten days he walked out of the hospital perfectly well. He remained free from pain for nearly two years, and then disappeared from observation.

The following cases, selected from a large number, will serve to further illustrate the value of this plan of treatment.

Case II.—Mrs. S., thirty-three years of age. Pain in the entire course of the right sciatic nerve of six months' duration. In the beginning, various lines of treatment had been tried, and subsequently a long splint was applied and retained in position for three weeks, and she was kept in bed for five weeks. An epidural injection had also been given without benefit. In all, some temporary relief was obtained, but she rapidly became worse. At the time of my first examination on May 8, 1913, there were tenderness and pain with radiation on pressure at the sciatic notch, over the course of the nerve in the thigh, and at the head of the fibula. Extreme pain on hyperextension of the extremity. Achilles reflex feeble.

May 10, injection of 120 c.c. This was followed by some pain during the night at the site of the injection.

May 11. The pain has disappeared, and she is able to stand and walk without any difficulty.

May 14. Remains free from spontaneous pain, although some pain is produced by deep pressure over the nerve. No pain on hyperextension. Injection of 120 c.c.

May 23. Slight pain in the leg below the knee. Injection of 110 c.c. at sciatic notch and 20 c.c. over the peroneal nerve.

June 4. Still has some slight tenderness at notch, and slight pain on hyperextension. Injection of 60 c.c., at notch, and 10 c.c., at the peroneal nerve.

Between the first and last injection, she was always able to walk about, slept well, and frequently travelled from Long Island to New York without discomfort. No further treatment was required, and she has remained well up to the present time. In all, four deep injections were given within a period of four weeks.

Case III.—Mrs. G., forty years of age, examined in January 1912. She had three mild attacks of sciatica at varying intervals for several years. Present attack is of three months' duration, and she has been confined to her room, either in bed or on a lounge all of this time. She complains of pain in the left lumbar region and in the entire course of the left sciatic nerve, and is unable to stoop without pain. There is a spastic scoliosis, with slight general muscular atrophy of the left lower extremity. There are exquisitely tender points with radiation of pain in the entire course of the nerve, over the left lumbar region, and at the sciatic notch. Extreme pain on hyperextension of the extremity. The knee-jerk is exaggerated. No ankle clonus. Achilles reflex feeble. Rectal examination reveals tenderness and pain on pressure in the neighborhood of the nerve below the pyriformis muscle. On February 2, 1912, she received the first injection of 90 c.c.

Feb. 16. The sharp pains had subsided within twenty-four hours after the first injection, but pain on hyperextension is still present although very much diminished. Injection of 100 c.c.

Feb. 21. Very much improved. During the last two weeks she has been able to walk about her room unassisted. Injection 100 c.c.

March 8. Only slight pain in the distribution of the peroneal nerve. She has resumed her household duties, and goes out walking daily, which necessitates going down and up four flights of stairs. Injection of 10 c.c. at the peroneal nerve. She has since remained free from pain, and made a complete recovery. In all, three injections were given, extending over a period of about four weeks.

Case IV.—B. R., age 43, tailor, admitted to the Lebanon Hospital January 24, 1913. Right sciatica.

Duration one year. He is unable to walk or stoop without extreme pain. Pain on hyperextension of right lower extremity. Tenderness and pain over the lumbar branches of the right sciatic nerve, at the sciatic notch, and over the course of the nerve. Achilles reflex absent. Injection of 110 c.c.. Within twenty minutes he was able to walk back to bed unassisted. He had some slight pain during the night. The following day he was free from pain, and was able to walk about and perform all movements of back and extremity without pain. He was discharged cured three days later without further treatment.

This is a typical history of many similar cases in which only one injection was required. Many others could be cited, but their repetition and similarity as to symptomatology would prove monotonous. In my neurological service at the Lebanon Hospital this treatment of sciatica has been a routine measure during the last few years. It has been a very common experience for me to see men with sciatica, who have been incapacitated for several months without securing adequate relief from the usual forms of treatment, rapidly relieved of pain and restored to activity by this method.

The assumption that sciatic pain is always a symptom either of arthritis at the hip or sacroiliac joint, or of pelvic disease, or that sciatic perineuritis is a nonentity, and that all cases of so-called sciatica are due to hip-joint disease as claimed by a recent Brtish writer, Dr. William Bruce, depends entirely upon the viewpoint of the observer and the type of cases he is accustomed to treat, especially among those appearing at an orthopedic clinic or hospital. The now well-established fact, based upon the clinical experience described in this paper, is adequate refuation of the unwarranted and preposterous statements just mentioned.

In the one hundred and sixty cases herein reported, there was no evidence of joint or pelvic involvement, and the correctness of the diagnosis was beyond doubt. The fact that many of these patients were rapidly and permanently cured by a single injection in the neighborhood of the painful sciatic nerve, is ample evidence of the affection being limited to that circumscribed area.

In conclusion it may be said that sciatica, whether a symptomatic neuralgia or the result of a perineuritis is admittedly a very intractable and painful affection often persisting for months or longer. After a large experience with all of the available and conventional remedies, the method herein described has proved, in my hands, the most valuable therapeutic acquisition developed within recent years. From an economic standpoint, it is superior to many other forms of treatment, inasmuch as in the majority of instances it rapidly relieves the pain, and the sufferer is soon enabled to return to his customary vocation.

TREATMENT OF SCIATICA BY EPIDURAL INJECTION OF SALINE SOLUTION.*

By ISRAEL STRAUSS, M.D.,

NEW YORK.

(From the Neurological Service of the Mount Sinai Hospital.)

Cathelin of France was the first to suggest the introduction of drugs into the epidural space. He made a thorough anatomical study of this space, of its relations, and its blood supply. He found that it contains, in addition to nerve roots and fat, a richly vascular venous plexus, which facilitates the rapid absorption of drugs.

The epidural space in an adult begins at the lower edge of the first sacral vertebra, where the dura ends. It extends down to the sacrococcygeal articulation. At this level the injections are made. There are certain landmarks by which this opening, the foramen sacrale superius, may be identified. It lies at the end of the crest made by the spines of the sacrum. It has the shape of an inverted V or U, and is about 1 cm. wide and from 1½ to 2 cm. in length. It is bordered laterally by two prominences, the cristæ sacrales laterales, which are usually easily felt by the finger. The opening is covered by a dense fibrous ligament, the ligamentum sacrococcygeum. The opening lies generally 2 cm. above the end of the gluteal fold.

Technique.—The needle which is used for the injection should be about 8 cm. in length and about 1 mm. in caliber. It must be firm, or else it is apt to be broken when forced through the ligament. It is to be inserted to a depth of 6 cm. to reach the second sacral vertebra.

If possible, place the patient in the knee-chest position in order more easily to locate the landmarks. If this cannot be done because of pain, insert the needle while the patient lies on the side with the knees and the thighs flexed. In the latter position the landmarks are not so easily discerned and the gluteal fold usually points above the foramen. It may be difficult, if not impossible, to enter the epidural space of very stout persons, especially of stout women.

It has been my custom to anesthetize with novocaine the skin and tissue overlying the foramen and the ligament. In doing this one must be careful not to cause much swelling, which might obliterate the landmarks. After pushing the needle through the skin considerable resistance is met at the ligament. Once this resistance is overcome the needle glides into the epidural space. If the patient is in the knee-chest posture the needle is inserted into the ligament at an angle of twenty degrees with the body. After it has passed through the ligament the needle is held so that it is horizontal to the body. Before injecting, it is well to be certain that neither veins nor dura have been pierced. If only saline solution be used no harm would be done if either of these structures be pierced.

The injection consists of warm sterile physiological saline solution. To the first 10 or 20 c.c of saline is added 0.3 of novocaine with suprarenin, and a few minutes are allowed to elapse after their injection to obtain the full benefit of their anesthetic effect. In all 60 to 80 c.c. of solution are injected at a time. This is a larger quantity than has been used by others, but I find it acts well and does no harm. I have injected as much as 130 c.c., but such an amount is unnecessary. Occasionally when large amounts are injected a swelling develops along the outer border of the sacrum, which is apparently due to the fluid escaping along the nerves through the intervertebral foramina.

I have shown that this occurs by radiographs of epidural injections of collargol. In fact, Cathelin injected mercurial preparations in order to reach the nerve roots. The procedure, if carried out as outlined, is accompanied by very little pain and the patient merely complains of an uncomfortable pressure in his lower spine. Occasionally he may have a sensation of sharp, shooting pain down the affected leg at the beginning of the injection.

*Read at a meeting of the Medical Society of the County of New York, December 28, 1914.

If no novocaine is used, and some have used merely saline solution, there may be some pain for about one hour after the injection. More or less complete anesthesia of one or both extremities has occasionally followed the injection, lasting not longer than forty-eight hours. In one case the knee-jerk disappeared after the injection. No injury to the nerves has been reported following an epidural injection. This cannot be said of the perineural injection of the sciatic nerve.

Type of Case Injected.—On the service of Dr. Sachs we have not treated acute cases of sciatica by this method. These have generally yielded promptly to rest in bed, to the constant application of a large flaxseed poultice, and to the administration of 40 or 50 grains of aspirin or 80 grains of novaspirin daily. Epidural injections have been practised in subacute and chronic cases.

Nineteen cases have been treated and thirty-six injections have been made. The duration of the sciatica was as follows: Five had suffered for one month, one for two months, seven for from three to nine months, and two had had recurrent attacks lasting over a period of two years.

Eight of the cases received one injection, nine received two injections, and two had three injections. One of these was a very marked case of sciatica scoliotica in the service of Dr. Manges, which was cured by two injections. Some of the patients had sensory disturbances and changes in the reflexes, which indicated radiculitis, a condition to which later reference will be made.

The most difficult cases to cure are those complaining of pain in the outer aspect of the leg and foot. One bedridden case of radiculitis due to secondary involvement of the nerve roots in a disease of the sacroiliac synchondrosis was so relieved of his sciatic pain that he was able to submit to the fixation of his leg and pelvis by a plaster cast.

The procedure has been of benefit in diagnosis. In two cases we have been able to exclude sciatic nerve disease by the failure of the injection to give relief and the subsequent course of the disease substantiated our diagnosis.

Rationale of the Treatment.—I confess that I am somewhat at a loss to explain the *modus operandi* of the injection. We are in the same position as regards the effect of the perineural injection. We are ignorant of the pathology of sciatica. Hence any theory about the action of the fluid must be pure speculation. We are accustomed to divide sciatica into two classes: sciatic neuralgia and sciatic neuritis. Cases of the first variety present no clinical symptoms pointing to nerve inflammation, except possibly tenderness along the course of the nerve. Those of the second variety present changes in the reflexes, changes in the sensation and motion, and even changes in the muscles.

In recent years Déjerine and his school have proved that many of these cases are due to a neuritis of the nerve roots forming the sciatic nerve. They have applied the term radiculitis to this class of cases. The diagnosis is based upon the fact that the distribution of the hypesthesia or the hyperesthesia is of a root character. This has probably been overlooked by us, especially in the milder cases. Careful clinical examinations will undoubtedly prove that many cases of sciatica are cases of radiculitis. If this is so, it would give additional support to the plan of treating "sciatic neuralgia" by epidural injections.

116 West Fifty-ninth Street.

MEXICAN TYPHUS FEVER.

By HENRY C. MICHIE, JR., B.S., M.D.,
CAPTAIN, MEDICAL CORPS, U. S. ARMY.

Definition. — An acute infectious disease of unknown origin, and transmitted by the body louse during the febrile stage. Characterized clinically by a sudden onset of severe pain in the head, neck, and limbs, continuous temperature for twelve to fourteen days, ending by crisis, and the pathognomonic typhus rash. Characterized pathologically as a hemorrhagic septicemia.

History.—Ancient History.—Typhus fever has been known to man since the days of Hyppocrates, who applied the term to a mental state characterized by stupor. However, not until 1829 was it recognized as a distinct disease, when it was so differentiated by Gerhard. At that time it was more common and caused more deaths than typhoid fever, the disease wherewith it was often confused. In the early days, its appearance in prisons and the maritime business was of the gravest importance.

The modern history dates back to about 1881, when the blood was looked upon as containing the virus; at this time Klebs described a bacillus, and Mott a micrococcus-like body. In 1892, Calmet clamed to have found a flagellated body; in 1893, Brühl a diplococcus, and in 1903, Gottschlich described a babesia as the cause of typhus. Also in 1903, Krunpecker described inclusion-bodies as probably being associated with the specific etiology. We owe the first data of great importance to Nicollé, Comte, and Consier, who in 1909 reported the successful transmission of typhus from monkey to monkey by the bite of the body louse (*Pediculus vestimenti*). This method of transmission was confirmed in 1910 and 1911 by Ricketts and Wilde, and by Anderson and Goldberger, working independently in Mexico City. They successfully passed the virus from monkey to monkey, man to monkey, and from man to peon, by this means.

The specificity was further proven by the sad instance of the late H. T. Ricketts—a master worker and martyr to science—who lost his life from typhus while investigating the disease in Mexico City, after being bitten by an infected body louse, while incubating them in a test tube under his arm.

Etiology.—Geographical Distribution. Mexican typhus fever does not occur in low altitudes, as, for example, that of Vera Cruz, a sea-level port, but may be found in any locality in Mexico having an altitude of 2,000 feet and over. It also occurs in some lower altitudes during the colder months. This is accounted for by the breeding characteristics of the body louse, which does not live in warm climates. Typhus is endemic in the great central plateau of Mexico, and the cities of greatest importance to Americans are Jalapa, Orizaba, Cordova, Mexico City, Puebla, Chihuahua, Pauchuca, Toluca, Zacatecas, San Luis Potosí, Guadalajara, Guanajuato, Aguascalientes, Torreon, and Parrel. The disease is reported present in these cities from time to time, and in Mexico City at present. In some of these cities typhus occurs the year round. In Mexico City there were over six hundred cases reported during one month of 1910.

Zoological Distribution. Typhus has not been found to occur naturally in any lower animal, neither have infected insects been found in nature. Certain species of monkeys, and also guinea pigs, have been infected by blood transfers.

Race. Local physicians say that foreigners are

most susceptible, and have a higher death rate than the natives, as well.

Age, sex, habits, and occupation play no part other than increasing or diminishing the liability of exposure to infected lice.

Climate and season. In colder climates, higher altitudes, and during the colder months of the year, typhus is endemic over a large area in Mexico. The greatest number of cases occur between October and March, but, as before stated, there are some places in which typhus is present the year round, as for instance Mexico City. At an altitude of two thousand feet this disease may be expected anywhere in the Republic; it is encountered over the entire grand central plateau, and in some of the cities of lower altitudes typhus occurs only in the cold months. This peculiarity has its explanation in the breeding characteristics of the body louse.

Heredity and Immunity. The former plays no part in the spread of typhus fever, as there is no such thing as hereditary typhus. Immunity is conferred by one attack, and I have been unable to find a case on record where there has been a recurrence of the disease. The organism (?) is present in the blood during the febrile period, and not longer than two days after the temperature falls to normal, therefore there are no chronic human carriers.

Transmission. It has been well recognized since 1910, that typhus fever is transmitted by the bite of infected body lice. The louse itself becomes infected by feeding on patients suffering from this disease, during the febrile period. At present, this is the only way known in which the louse becomes infected. The insect probably remains infectious through its entire natural life, but Anderson and Goldberger have proven that eggs of infected adults do not contain the virus, therefore adults do not transmit the infection to their progeny, as is the case with the tick (*Dermacentor venustus*) of Rocky Mountain spotted fever, where infected adults transmit the virus through the entire life cycle. This is an important epidemiological factor to be considered in dealing with these two diseases. Salivary glands of the louse contain the virus, but pharyngeal secretions of patients are negative; it is also believed, that the urine and feces are negative, as in Rocky Mountain spotted fever, a disease which typhus closely resembles.

The flea (*Pulex irritans*), bedbug (*Cimex lectularius*), and house fly (*Musca domestica*) do not transmit typhus, and it is improbable that either biting flies or mosquitoes play any part in the transmission.

The virus is present in the blood of patients suffering from typhus from the first appearance of fever until the crisis, and it may be present for thirty-six hours thereafter. This has been proven by blood transfers into susceptible lower animals, and even into peons from infected patients.

Lice. (Genus, Pediculi; suborder, Parasita; order, Hemiptera; class, Insecta.) The insects are parasitic during their entire metamorphosis. There are three species that occur on man, namely, the head louse (*Pediculus capitis*), the eggs of which are small, white, hard, and torpedo-shaped, with one end cut off; and are commonly known as "nits." These "nits" are cemented to the hair by a powerful glue, and can be removed only with great difficulty. The adults are found crawling on the scalp; their presence may be suspected if the scalp shows irritation, especially if hemorrhagic spots, marking bitten areas are found, and if "nits" are seen on the hair. They can be most easily found with a fine toothed comb, but care must be exercised not to mistake bits of dandruff or empty shells for "nits." Anderson and Goldberg have proven that this parasite can transmit typhus, having accomplished this transfer from monkey to monkey; but judging from its wide distribution and great chances of changing hosts, as well as being very common in localities where typhus is unknown, it is not probable that the head louse is a usual carrier of the disease.

The body louse (*Pediculus vestimenti*) is the insect that disseminates typhus fever, after feeding on a patient that is suffering from the disease. No naturally infected lice have been found in nature, and it is not known just exactly how this disease is perpetuated. Eggs of the body louse are laid in the seams of clothing, and the parasites are most commonly found there too. They migrate to the body in order to feed by engorging with blood, leaving the bitten site marked by a hemorrhagic spot. These spots are commonly seen on the back, neck, and abdomen.

The body louse does not breed in high temperatures, as for example in Vera Cruz, and that accounts for the absence of typhus in that city. For experimental work, lice are kept at a temperature between 16° and 20° C. between feedings, or else they die; this fact was the cause of the failure of the early experiments. As one ascends from the sea level into higher altitudes, lice are encountered, and it is there in Mexico that the dangers of typhus commence.

The crab louse (*Pediculus pubis*), the third and last species of this genus, is much the smaller of the three species, and occurs most commonly on the pubis, but also on other parts of the body, where there are short, stout hairs, as the axillæ, eyebrows, and chest. It is probably the most widely distributed member of the pediculi, and is apparently uninfluenced by changes in the atmospheric temperature. The eggs, as those of *Pediculus capitis*, are cemented to hairs, and the adults are found either with their heads embedded, or crawling free on the skin. There is no record of experimental transmission of typhus by the crab louse, but since the other two species act as a biological carrier, it is not improbable that the *Pediculus pubis* may act in a similar manner.

Lice are parasitic during their entire existence, feeding intermittently and solely on blood. They remain closely attached, and do not change their host readily as some of the more active parasites do, for example the flea. However, changes are made by contact and through change of wearing apparel. Pediculi are flat, elongated, wingless insects, with a small head, and three pairs of short stout legs, each leg ending in a strong claw. The proboscis is short and strong; it contains a stylet which is divided into three parts, adapted for piercing the skin, injecting an irritating fluid to cause hyperemia, and for sucking up the blood. Structurally the insect is divided into head, thorax, and abdomen; all of the legs are attached to the thorax. Lice usually move sidewise, and do not travel far. This is an important factor, as it reduces the spread of lice from person to person. The females are larger and more common; each female lays about twenty eggs at a time, which hatch in from six to fifteen days; the young are paler in color, but otherwise resemble adults in structure. They molt their skin about four times before maturing, feeding between molts. There are several generations each year,

depending on the temperature, but the life cycle has not yet been thoroughly worked out.

Adults are easily destroyed, but the eggs are very resistant. If a head is badly infested, it is best to clip the hair short and throw it into the fire, wash the scalp well with cocculus indicus, or kerosene and olive oil in equal parts. One application is usually enough to destroy the parasites.

A complete change of clothing and a general bath with a 1:1000 solution of bichloride of mercury is best for the *Pediculi vestimenti.* Immediate action must be taken to destroy the parasites and eggs remaining in the clothing, which is best done by boiling where means are available.

The crab louse can be destroyed by a kerosene sponge and inunction of blue ointment.

The louse acts as a biological carrier of typhus, requiring about eight days after engorging with infected blood before being able to inoculate a nonimmune. When placed upon man, if ready to feed, will readily attach and engorge with blood.

Specific Cause.—No specific cause has been found, but by immunity and cross immunity tests not only has the specificity of the disease been established, but Mexican typhus, old world typhus, and "Brill's disease," have been shown to be due to the same cause, the strain only differing in virulence. In view of the fact that a part of the cycle (?) is passed in man, and part in an invertebrate, requiring a definite time, it seems most probable that the specific cause is a protozoon.

Many things have been described as the cause of typhus, the latest body described is a pleomorphic bacillus, 0.9-1.93 x 0.2-0.6 M., described by Harry Plotz of New York, in the *Journal of the American Medical Association*, 1914, in which he claims to have recovered this organism in eleven out of twelve cases of "Brill's disease" and typhus. He further claims to have produced the disease in guinea-pigs by intraperitoneal inoculation with this bacillus, recovered it again, and obtained positive complement fixation tests after the crisis. From the description given, this bacillus resembles the Ricketts' bacillus, described by the late H. T. Ricketts, in 1909, while investigating Rocky Mountain spotted fever in Montana; later on he stated that this bacillus occurs in the blood of any case of hemorrhagic septicemia.

Pathology.—A body dead of typhus will show an early decomposition and late rigor mortis. The skin eruption remains after death, much accentuated on the back, neck, and legs—the dependent parts—where the eruption becomes confluent, forming large areas. This is due to the stagnation and poor aeration of the blood before death; these spots are of a dark blue hue. In very severe cases there is but little emaciation, due to insufficient time, but is marked in milder cases, where the illness is of longer duration.

The pathology is characteristic of a severe hemorrhagic septicemia, the venous side is engorged; the lymph nodes, liver, spleen, and kidneys are enlarged and hemorrhagic. The meninges show irritation and the lungs are edematous but show no consolidation. Myocardial degeneration, due to toxemia, sometimes occurs. The blood is dark and time of coagulation increased, leucocytosis, 18,000 to 50,000, with polymorphonuclears 90 per cent., large mononuclears and lymphocytes decreased, and eosinophiles often absent. The red blood corpuscles and their hemoglobin are increased.

The virus is present in the blood from the second day to not longer than thirty-six hours after the crisis. Up to the present it has refused to grow on culture media, and is not destroyed by freezing for a week. A temperature of 55° C. for fifteen minutes will destroy the virus. Anderson and Goldberger state that the virus will pass through a Berkefeld filter at some stages, but not at others, which indicates a change in the morphology. They do not state the size filter or the length of time used in endeavoring to pass it through. This is important, as for example the spirocheta pallida will pass through if left in a No. "N" Berkefeld filter for twenty-four hours. Macerated bodies of infected lice in physiological salt solution, when injected into a nonimmune, produce the disease; this is not true with macerated eggs of infected adults. The point of destruction of the organism by the maceration is not considered.

Gangrene of the fingers, toes, nose, and possibly the scrotum, occasionally occurs in cases where the virus is virulent, and the patient lives into the second or third week. The exact cause of this gangrene is not known.

Signs and Symptoms.—These vary from year to year with the severity of the epidemic, which also varies, being in some instances so mild as to require laboratory findings to differentiate it from a mild attack of typhoid, while in others quite severe, causing death before the characteristic eruption appears. Between these two extremes there are varying degrees, and it is in this intermediate class that the largest number of cases occurs.

For study, the disease can be divided into three stages, (1) Stage of invasion; (2) Stage of eruption; (3) Stage of reaction or decline.

1. Stage of Invasion.—After an incubation period of ten or twelve days the disease is ushered in rapidly with a chill, high temperature, severe headache, and pain in the neck, back, and legs. The bowels are constipated, respiration and pulse increased; the pulse is bounding but not dicrotic. There is an early prostration, and the patient takes to bed very soon. Bronchial irritation and conjunctivitis are common, also nausea and vomiting. The face is flushed, and the temperature rises rapidly to 104° F., with but limited remissions. Meningeal irritation develops early, and is manifested by headache and early delirium. There is leucocytosis with increase in polymorphonuclears; absence of eosinophiles is an unfavorable sign. These findings increase until about the fourth day, when the eruption appears. Early albuminuria is a concomitant sign.

2. Stage of Eruption.—Reckoning from the first appearance of fever the typhus eruption develops about the fourth day; first on the chest and abdomen, spreading from here over the entire body, except the face, palms, and soles. There is an irregular, deeply seated, subcuticular mottling, not disappearing on pressure, and a papulo-rose spot eruption, somewhat resembling measles. The latter becomes hemorrhagic (petechial) by the second day, and does not disappear after death. As the disease advances, these petechiæ often coalesce on dependent portions of the body, forming large, dark, dusky lesions (ecchymosis) not affected by pressure.

The temperature ranges from 103° to 106°, with but slight morning remissions. The brain symptoms become more marked, muttering delirium, carphology, and subsultus tendinum often give way to stupor. The body presents a dusky appearance, and characteristically so about the mouth; this is due

to the dark color of the blood. The pulse becomes more rapid, and the bowels and bladder act involuntarily. The leukocytosis increases, sometimes reaching as high as fifty thousand.

3. Stage of Reaction or Decline.—This is marked by a crisis, which occurs between the twelfth and fourteenth day, usually at an early morning hour, and is attended by the usual signs and symptoms of a crisis. On the afternoon of the same day the temperature will rise again to about 103°, only to be followed next day by a drop to normal, and to remain so. Following, the general condition improves, and convalescence commences; this latter takes about two to four weeks. No relapses are reported, and generally the patient makes a complete recovery.

Should the crisis not occur by the fourteenth day, the condition should be looked upon as very serious; pseudo-crisis is reported occurring in many fatal cases. In these precarious cases the crisis does not occur, the general condition becomes worse, the pulse becomes weak and rapid, and the two heart sounds are alike. The amount of urine is decreased, and the percentage of albumin increased, suppression is not uncommon in these cases. The eruption is profuse, blood dark, temperature high, and there is leukocytosis with absence of eosinophiles. Urine and feces are passed involuntarily, the skin is dusky, hematogenous jaundice appears (first seen in the conjunctiva), edema of the lungs, accumulation of mucus in the pharynx, profound stupor, and the patient dies of toxemia. In very severe infections the patient may succumb in the first four days, in others, between the tenth and fifteenth day. Gangrene of the fingers, toes, nose, and possibly of the scrotum sometimes develops shortly before death.

Treatment.—There is no specific treatment for typhus fever. Immune sera and vaccination are of no practical value. The symptomatic and dietetic treatments consist in resting the patient in bed on liquid diet, keeping the bowels open by the use of purgatives and enemata, hydrotherapy for the temperature and headache, cardiac stimulants in the advanced stages, if the heart begins to fag; whisky, digitalis, and camphor are probably the best. If strychnine is used, it must be repeated often enough to keep up the stimulation after it has once been started, using about one-thirtieth of a grain every four hours.

The writer believes sodium citrate in full doses, or the Sternberg yellow fever treatment, would be beneficial. The latter consists of sodium bicarbonate, 150 grains, mercury perchloride, one-third of one grain, and two pints of water. Of this solution 1½ ounce is given every hour. The amount of water taken should be pushed to the limit, probably best in the form of lemonade, to increase the elimination of toxins.

Salvarsan has been used in the treatment of typhus with varying results.

Prognosis.—This depends on the severity of the epidemic, and resistance and age of the patient. The number of recoveries is much greater in children, and the mortality is in direct proportion to the age. In mild epidemics the mortality is estimated at 5 to 20 per cent.; in the severe from 30 to 50 per cent. The mortality is also reported to be higher among foreigners.

Unfavorable signs are absence of eosinophiles, severe petechiæ, gangrene, lung signs, tendency to suppression, jaundice, and facial cyanosis. The increase of eosinophiles and large mononuclear leukocytes are favorable signs. Death has been reported on the second or third day in malignant cases; positive diagnosis would be very difficult or impossible in these cases without blood transfers into susceptible animals.

Sequelae.—Bronchopneumonia, nephritis, meningitis, and gangrene of the fingers, toes, nose, and possibly scrotum, are reported as being the most common complications and sequelae.

Prophylaxis.—For a long time typhus has been associated with dirt and filth. Many years ago Hirsch said that "the history of typhus is the history of human wretchedness." The prevention of this disease can be summed up in these few words: avoidance of being bitten by infected lice. Prevention may be carried out in the following manner:

1. Cleanliness of the body and linen.

2. Avoidance of native shacks, washerwomen, and association with dirty people in infected zones.

3. If infested, prompt and radical means for the extermination of the insects should be instituted.

4. Thorough inspection of all cases in typhus localities, regardless of their condition before admission to hospital.

5. Scrupulous cleanliness in hospitals, with frequent inspections to the end of preventing lice from gaining headway in the building.

6. In case lice are found, all linen should be boiled, the wards fumigated with hydrocyanic acid or dioxide, and the heads and bodies of the patients examined.

7. If it becomes necessary to enter infected places, the person should not touch the bed, sit down, or lay down his hat or coat; he should step quickly, roll up the bottoms of the trousers, and search his clothing for lice after leaving the building.

8. When a typhus case is admitted to the hospital, the patient must be most carefully examined for lice before being admitted to the ward. He should be placed in a bed most positively free from lice, and as an additional precaution, covered with a mosquito bar tucked in around the mattress.

9. Should typhus develop in a command, a thorough search for the louse should be instituted immediately, examining as many of the troops as necessary, especially those men who were in intimate contact with the patient. If thought advisable, the contacts should be quarantined in a pediculus free place during the incubation period.

10. Entering buildings, wherever possible, in typhus bearing localities should be avoided. If buildings must be used, new ones should be selected. The number of cases would be greatly reduced, however, by using buildings as new as can be found, and by thoroughly renovating them before being occupied.

At present there is no tangible reason for considering the crab louse in connection with the transmission of typhus, but the other two species of this genus doubtlessly transmit it, and the association of the *Pediculus vestimenti* with the disease has been conclusively established. Every precaution must be taken to prevent the introduction of these insects into places where troops are quartered. The following illustration gives a clear example of the specificity of typhus, being transmitted by the louse. Belem Jail, the city prison of Mexico City, which is overcrowded with filthy, lousy criminals, and shelters tens of thousands of infected lice, is one of the principal sources of infection in that district. Throwing lice, not necessarily infected, upon the clothing or into the pockets of innocent victims, as a practical joke, is not unknown there. On the other

hand, the government penitentiary, a model prison, under up-to-date sanitation, has never produced a case of typhus fever.

In view of the fact that infected lice do not transmit the virus to their eggs, and that the virus is not present in the blood of patients, once the temperature becomes normal, there must be some other carrier of typhus than man and louse. Is it not possible that typhus exists in a chronic state in some lower animal, and is accidentally transmitted to man through the bite of the louse or some other insect?

In preparing this article the following works have been consulted: "Practice of Medicine," Osler; "Tropical Diseases," Chalmers and Castellini; "Public Health Bulletins," U. S. Public Health Service; "Publications" of Ricketts and Wilde; letters about typhus received, in response to inquiries, from many doctors in Mexico, for which I wish especially to thank Drs. Prestly and Goodman of Mexico City, and Dr. Hoskins of Pachuca. From reading the available literature on typhus and having been experimentally associated with Rocky Mountain spotted fever in Montana, several additional suggestions were added to what has already been written on the disease.

THE DANGER OF DELAY IN THE DIAGNOSIS AND TREATMENT OF INTUSSUSCEPTION IN INFANCY.

By EDWARD W. PETERSON, A.M., M.D., F.A.C.S.,
NEW YORK.

It took years of educational efforts to place the treatment of appendicitis upon a purely surgical basis. To-day there is a general condemnation if a patient with appendicitis is allowed to die without surgical treatment. Acute intussusception is far more dangerous to life than appendicitis and, theoretically at least, belongs exclusively to the surgical field. Experience in this disease forces one to recognize the hopelessness of expectant treatment and the relative futility of all aerohydrostatic measures.

In intussusception, the clinical picture is more constant and unvarying, and the symptoms are more uniform and characteristic than in any other type of intestinal obstruction. In spite of this, no class of cases is more often unrecognized and more habitually mismanaged and maltreated. Because of failure to make a diagnosis or delay in the recognition and treatment, the mortality in this disease is disgracefully high. The figures would probably be better if spontaneous disinvagination had never occurred and if no case had ever recovered after sloughing of the intussusceptum. It is unfortunate, too, that hydrostatic pressure and gas or air inflation succeed in a limited number of cases, for such measures are often persisted in until the time for a successful operation has passed. It is not the purpose of this paper to decry aerohydrostatic treatment, but rather to emphasize its limitations. Ladd collected 216 cases treated in this manner, with failure in 81 per cent. Clubbe, in 173 cases, was able to reduce the invagination in but sixteen instances.

Mortality.—Leichenstern, in a study of 557 cases of intussusception, places the mortality at 73 per cent., and during the first year of life at 88 per cent. Kock and Orrum, in a study of 400 Danish cases, give the mortality in the first year of life at 60 per cent.

J. S. Stone[1] reported the cases of intussusception treated surgically in the Children's Hospital, Boston, for the four years previous to the publication of his paper. There were 8 cases, with 7 deaths and 1 recovery.

In the Infants' Hospital, Boston, from 1898 to 1908, there were 8 cases, with 7 deaths and 1 recovery.

Codman[2] states that in the Massachusetts General Hospital, from 1897 to 1907, there were 11 cases in infants, with 9 deaths; 1 operative recovery in a patient who succumbed four weeks later when operated upon for hernia; and 1 recovery in a case of doubtful diagnosis.

Ladd[3] reports 20 cases operated upon by J. S. Stone and himself in the Children's Hospital, Boston, during the past four and a half years, with 9 deaths and 11 recoveries.

Francis Allen[4] reviews 27 cases occurring in the Children's Hospital, Philadelphia. There were 16 deaths and 11 recoveries.

Erdmann has operated upon over fifty cases of intussusception, with highly successful results, but his statistics are not available.

In the Post-Graduate Hospital, Babies' Wards, there have been admitted during the past ten years 32 cases of intussusception—29 in infants and 3 in older children. Of these 32 cases subjected to operation, 16 died and 16 recovered. Through the kindness and courtesy of Dr. Samuel Lloyd, on whose service the patients were admitted, the author had personal charge of the 19 cases whose histories appear in the accompanying charts. The patients ranged in age from six days to thirteen months. All were breast-fed, healthy, well-nourished infants, with one exception (No. XII, Esther B., Group I). In the physical examination an abdominal tumor was palpated in every instance. The invagination—unless stated otherwise—was in the ileocecal region. Every case seen within 48 hours of the onset of symptoms was saved by laparotomy. In several instances the symptoms had lasted even longer in patients who recovered. The fatal cases were all brought in late and, for the most part, were considered hopeless, but none was refused operation.

These statistics seem bad, but if we seek a reason the answer is simple—namely, failure or delay in the diagnosis, or improper treatment, or procrastination in advising surgical measures. In many of our own cases, it was only after the failure of medical treatment and mechanical measures to reduce the invagination that the patients, as a last resort, were sent to the hospital for operation. The fault rarely rests with the family in refusing operation, but lies with the physician who fails to realize his responsibility in the care of this peculiarly serious affection.

In a study of this disease the most striking point is the wide difference between the mortality in the early and in the late operations. The statistics of greatest interest are those giving the time of treatment (either surgical or otherwise) after the onset of symptoms; and almost invariably one is impressed with the fact that "cured" cases were diagnosticated and treated early. Cases recognized and treated during the first twenty-four hours give a mortality in experienced hands of not over 10 per cent. Cases treated after two days have passed, with but few exceptions, have but little chance of recovery.

Clubbe's work in intussusception,[5] quoted in many recent articles, should be an inspiration to every pediatric surgeon. He treated 173 cases, 16 of which were successfully reduced by enema. Of the

GROUP I—MANUAL REDUCTION OF INVAGINATION.

Name	Date	Age	Diet	Duration Illness	Condition on Admission to Hospital	Treatment	Condition After Operation	Results	Remarks
1. Elsie M	June 2, 1905	8 mos.	Breast	About 48 hours	Fairly good.	Laparotomy. Easy reduction of ileocecal intussusception. Appendix removed	Slight shock. Quick recovery. Very little secondary enteritis.	Cured. Discharged on seventh day.	Reported in MEDICAL RECORD Sept. 12, 1908.
2. Michael L.	May 31, 1906	12 mos.	Breast	3 days	Very toxic. Temp. 104. Pulse 136. Prognosis bad.	Laparotomy andeasy reduction.	Pronounced toxemia. Temperature 105.4.	Died 9 hours after operation.	
3. George B.	Sept. 16, 1907	5 mos.	Breast	3 days	Poor condition.	Laparotomy. Very difficult reduction. Serous coat tore in several places.	Profound shock and toxemia. Vomiting persistent. Temp. 107.8. Symptoms gradually cleared up.	Cured.	Reported in MEDICAL RECORD Sept. 12, 1908.
4. Samuel S.	Feb. 1, 1909	8 mos.	Breast	24 hours	Good condition. Between paroxysms seems normal. Temp. 100.	Laparotomy. Easy reduction of ileocecal invagination.	Moderate toxemia. Temperature 104.	Cured.	Convalescence uneventful.
5. Ethel G.	Feb. 24, 1910	11 mos.	Breast	About 36 hours	Fair condition. Temperature 101.8. Pulse 132.	Laparotomy. Moderately difficult reduction of entero-enterocolic intussusception.	Very little shock. Toxemia not marked. Temperature 103.4. Pulse 144.	Cured.	Double intussusception, commencing about 4 inches above ileocecal valve.
6. Joseph H.	Apr. 5, 1910	6 mos.	Breast	3 days	Prognosis bad. Very toxic. Temperature 104. Pulse 150.	Laparotomy. Difficult reduction.	Profound shock and toxemia.	Convulsions and death 5 hours later.	
7. Yelnick B.	July 1, 1910	7 mos.	Breast	5 days	Moribund. Pulse could not be counted. Temp. 107.6. Typical history cardinal symptoms, tumor easily felt.	Child lived less than an hour after admission. No treatment.	Not operated upon.	Death.	Autopsy not allowed
8. Milton H.	July 31, 1910	13 mos.	Breast and other food	4 days	Condition fair. Temp. 102. Pulse 120. Blood ex. showed 26,000 leucocytes: 89% polymorphonuclears.	Laparotomy. Colic intussusception of descending colon and sigmoid. Easy reduction.	Moderate toxemia and enteritis. Temperature 104.8.	Cured.	
9. Portanto B.	July 24, 1911	5 mos.	Breast	4 days	Apathetic. Very toxic.	Laparotomy. Exceeding difficult reduction of ileocecal invagination.	Marked shock and toxemia. Temperature 106.	Died 7 hours later.	
10. Ida W.	July 8, 1913	4 mos.	Breast	22 hours	Apparently normal except during paroxysms of abdominal pain. Typical history characteristic symptoms.	Laparotomy. Double intussusception (entero-ileocecal). Easy reduction. Appendix removed.	But little shock. Good condition.	Cured.	Admitted 8 hours after onset, but house physician did not recognize condition. Diagnosis of "intussusception" next morning by head nurse.
11. Blanche A.	Jan. 27, 1914	7 mos.	Breast	60 hours	Condition poor. Moderate toxemia.	Laparotomy. Very difficult reduction of ileocecal intussusception. Serous coat so badly torn could not be repaired. Gut mottled maroon color.	Severe shock and toxemia. Temp. 105.6. Remained high. Pneumonia (double) on 5th day. Fecal fistula on 6th day, which discharged for several weeks. Fistula healed March 3.	Cured.	Sent from hospital long before fistula healed. Kept under observation for several months. Recovery complete.
12. Esther B.	Apr. 11, 1914	4 mos.	Breast	3 days	Poor condition.	Laparotomy. Difficult reduction. Serous coat ruptured and was repaired.	Severe shock and toxemia. Fecal fistula on 7th day.	Improved. Discharged from hospital Apr. 27. Small fistula still open.	Suddenly died 1 week after leaving hospital. 3 weeks after operation. Cause of death unknown.
13. Seymour K.	May 15, 1914	8 mos.	Breast	2 days	Good condition.	Laparotomy. Easy reduction of invagination.	Very little shock and but slight reaction.	Cured.	Discharged 1 week after operation. On day of discharge developed German measles. Recovery without complications.

157 cases operated upon, his results are as follows: In the first 50 cases 25 deaths, 25 recoveries; mortality 50 per cent. In the second 50 cases 12 deaths, 38 recoveries; mortality 25 per cent. In the third 50 cases 4 deaths, 46 recoveries; mortality 8 per cent. In the remaining 7 cases there were 7 recoveries. In fact, in his last 25 cases, treated by laparotomy, there was not a death.

Giving full credit to Mr. Clubbe for his operative skill, what then is the secret of his remarkable success? The answer is: Early diagnosis and prompt surgical treatment. In his last 50 cases, the average time from onset of symptoms until operation was but seventeen hours. After forty-eight hours, in a considerable proportion of cases, the invagination is either irreducible or gangrenous, and resection of the bowel or enterostomy is required. Where either procedure is necessary, the mortality is frightfully high. When a search of literature reveals but ten successful cases in infancy, one appreciates Barker's remark that he had never seen recovery after resection in gangrenous cases, and never expected to see it. The fact that there have been ten successful resections, however, should counteract the view of older surgeons that gangrenous or irreducible intussusceptions were to be considered as hopeless.

Age and Frequency.—Intussusception is a cause of intestinal obstruction in about 30 per cent. of cases. While it may occur at any age, it is essentially and preeminently a disease of infancy. Probably 70 per cent. of all cases occur during the first year of life.

Symptoms and Diagnosis.—As has been stated, the clinical picture is so definite and characteristic that diagnosis rarely presents any difficulties. No other serious surgical affection of the abdomen is so easily recognized. The first examination of the infant will generally reveal the condition. At such a time, disinvagination is a simple matter and at-

Group II—Cases Requiring Resection or Enterostomy.

Name	Date	Age	Diet	Duration of Illness	Condition on Admission to Hospital	Treatment	Condition After Operation	Results	Remarks
1. Ida A	Apr. 28, 1904	4^2_3 mos.	Breast	About 50 hours	Temp. 102°. Pulse 146. R. 40.	Laparotomy. Resection of gangrenous intussusception. End to end anastomosis between ileum and ascending colon.	Profound shock and toxemia; also severe secondary enteritis.	Cured.	Reported in detail in Medical Record March 5, 1905.
2. Romeo M	July 5, 1906	4 mos.	Breast	$2\frac{1}{2}$ days	Apathetic and very toxic.	Laparotomy irreducible gangrenous ileocecal invagination. Resection and end to end anastomosis.	Profound shock and toxemia from which patient never rallied.	Died 3 hour after operation.	Reported in detail in Medical Record, Sept. 12, 1908.
3. Margaret H.	July 11, 1906	5 mos.	Breast	1 week	Almost moribund. Hopeless prognosis.	Laparotomy. Irreducible intussusception. Gut ruptured when attempt at reduction made. Enterostomy to prevent death on table.	Condition temporarily improved.	Died 17 hours later.	Reported in Medical Record Sept. 12, 1908.
4. Edw. McA	July 7, 1908	3 mos.	Breast	3 days	Very toxic. Temperature 103.	Laparotomy. Double gangrenous irreducible intussusception. Resection and anastomosis.	Never reacted from shock of operation.	Died 1 hour later.	
5. Henry I.	Feb. 4, 1910	6 days	Breast	Probably from birth	In collapse. Condition hopeless.	Laparotomy. Volvulus and double irreducible intussusception. Gut ruptured. Free fluid in abdom. cavity. Resection and anastomosis.	Never rallied.	Died just after operation.	Mother admitted for acute appendicitis developing after delivery. Condition of baby overlooked.
6. Willie G	Feb. 6, 1913	6 mos.	Breast	3 days	Profoundly toxic. Fecal vomiting. In collapse.	Laparotomy. Gangrenous intussusception ruptured when reduction was attempted. Resection and lateral anastomosis.	Never rallied from shock.	Died 4 hours after operation.	

tended with little risk to the patient. Generally speaking, a healthy, well-nourished, breast-fed infant is seized suddenly with severe abdominal pain, with more or less pallor, shock, and relaxation. Vomiting usually occurs at this time. Later, there is straining, and blood and mucus appear in the stools. With this typical picture, but one other symptom is necessary to settle the diagnosis—viz., the presence of an abdominal tumor.

After the first storm of pain is over, there follows a short period of calm, during which the infant may appear perfectly well. Later, however, the pain returns, is of an intermittent, paroxysmal nature, is accompanied by rhythmic straining, but not by the pallor and shock which ushered in the initial seizure. If the patient is seen during the "calm" period, unless the history is carefully considered, the diagnosis is apt to be overlooked.

Mucohemorrhagic stools commence in from two to twelve hours after the onset of the disease. After the first movement or two the stools contain no bile or feces and flatus is not passed. Vomiting is rarely a prominent symptom until late in the disease; when it occurs early and is persistent, it is significant of strangulation of the blood supply to the bowel. Rarely is it fecal.

In every case of intussusception there is present an abdominal tumor, but it is often difficult to palpate. Early in the disease, when relaxation and flaccidity are the rule, the abdomen may be examined with ease. Later, owing to rigidity and straining, but seldom to distention, palpation is unsatisfactory unless the examination is made under anesthesia. The typical sausage-shaped tumor of the text-books has been too much emphasized. It is rarely felt early and, when present, means that the intussusception has progressed to a considerable extent. More often, a rounded mass is felt, and it may occupy any portion in the abdomen. It is generally quite movable, and may resemble an enlarged gland. Where the tumor is oblong or sausage-shaped, it is curved, with the convexity directed toward the umbilicus. The mass may be felt to contract or relax under the hand. If the tumor cannot be felt abdominally, then bimanual rectal examination should be made in every suspected case. Under anesthesia one seldom fails to discover its presence. Clubbe in an examination of 173 cases failed to find a tumor in but two instances.

In the beginning of the attack the severity of the symptoms mentioned (pain, vomiting, mucohemorrhagic stools, etc.) depend upon the degree of strangulation rather than the fact that the bowel is obstructed. Later, in addition to obstruction and strangulation, toxemia develops as a result of injury to the bowel wall (particularly the mucosa) and from decomposition of the intestinal contents. The late picture is that which occurs in every variety of acute intestinal obstruction.

Differential Diagnosis.—Differential diagnosis presents little, if any, difficulty in the intussusception of infancy. Ileocolitis (acute dysentery) and the purpuric diseases have occasionally been mistaken for intussusception. In the former, there is fever and diarrhea, with mucus and blood. The stools contain bile and feces, and flatus is passed. No abdominal tumor is present. In the purpuric diseases, which, by the way, are rare in infancy, hemorrhage from the intestine may be a symptom. Hemorrhage elsewhere, however, gives the clue to the diagnosis. It must not be forgotten, however, that intussusception may develop as a complication of these diseases. Several cases have been reported as coming on during the course of Henoch's purpura. In these cases the diagnosis rests on the finding of the characteristic tumor of the intussusception. In any doubtful case where the symptoms are not urgent, a bismuth mixture may be injected into the colon and an *x*-ray picture taken.

Treatment.—The simplest, most successful, and the only certain method of treatment in intussusception is early laparotomy, with manual reduction of the invagination. Unless recognized early and treated promptly, the result is almost always fatal.

Spontaneous reduction has been known to take place. Cases have recovered after sloughing of the intussusceptum, firm adhesions forming at the neck of the intussusicipiens. Such results, however, are never to be awaited or expected. Like strangulated hernia and fulminating appendicitis, it is a condition demanding immediate operative interference.

The operation should be performed as quickly as is consistent with safe and thorough work, for infants do not bear prolonged operations well. As three-fourths of all cases originate in the ileocecal region, the incision, with its center slightly below the level of the umbilicus, should be made through or to the outer margin of the right rectus muscle. Some operators prefer the median incision when the tumor is felt low down on the left side. In relieving the intussusception, it is best to commence at the apex of the intussusception and carefully "back up" to the point where the invagination started. If traction is made on the proximal end the gut is apt to be torn at the neck of the intussuscipiens. If gangrene has occurred, or if reduction is impossible, resection and intestinal anastomosis should be performed. In all early operations, especially where the invagination occurs in the ileocecal region, it is a good plan to remove the appendix, for it may, in certain instances, be a causative factor in the production of the obstruction.

In closing the wound, one should reinforce the layer sutures of catgut with through-and-through tension sutures, as the abdominal wall is subjected to considerable strain.

The following points should be emphasized:

1. Intussusception in infancy presents a rather uniform and characteristic picture and should be recognized without difficulty.

2. Aerohydrostatic and mechanical measures can succeed in but a limited number of cases. Such treatment is not without danger.

3. Early laparotomy, with manual reduction of the invagination, is the safest, the simplest, and the most successful method of treatment.

DEEP ROENTGEN THERAPY AND ITS APPLICATION IN THE TREATMENT OF MALIGNANT GROWTHS.*

By SAMUEL STERN, M.D.,

NEW YORK.

RADIOTHERAPIST TO MT. SINAI HOSPITAL AND CHIEF OF THE RADIOTHERAPY DEPARTMENT, MT. SINAI HOSPITAL DISPENSARY.

The technique of the administration of Roentgen-therapy in malignancy, especially in deep seated lesions, has recently undergone such a radical modification that one may be permitted to speak of "deep Roentgen therapy" as one of the newer branches of roentgenology.

The chief modifications are based upon the following: (1) The use of aluminum filters; (2) Cross fire administration; (3) Massive doses; (4) The use of rays of a certain degree of penetration.

Taken separately, there is nothing radically new in any of the items mentioned, but carried out collectively, following a carefully worked out formula, it marks a radical departure in Roentgen therapy.

1 *Aluminum filters.*—In 1903[1] Perthes drew attention to the fact that it was possible to increase the penetration of the *x*-rays emitted from a tube, by permitting them to pass through an aluminum filter. This increase in penetration is due to the fact that the soft rays are filtered out by the aluminum, thereby materially increasing the penetrability of the remaining hard rays.

In 1904,[2] after extensive experiments, he showed that 1 mm. of aluminum absorbs approximately the same amount of rays as is absorbed by 1 cm. of animal tissue (except lung tissue) or by 1 cm. of water. These experiments probably laid the earliest foundation for deep therapy as applied to-day.

Improvements in technique gradually developed after this, but it was not until the valuable and exhaustive work done by Gauss and Lembcke[3] at the Freiburg school (published in 1912), solving the question of the thickness of filter to be used, dosage, proper degree of hardness of ray, etc., that the administration of "deep Roentgen therapy" received its most radical modifications.

The thickness of the aluminum filter that they found best adapted to treatment in deep seated lesions is 3 mm. In lesions situated nearer the surface, 1 or 2 mm. may suffice.

In addition, to avoid the secondary rays produced in the filter, it is advisable to use 3 or 4 layers of Satrap papier (thick photographic paper) and a flat loofah sponge filter, placed over the area to be treated.

2. *Cross fire administration.*—This simply means attacking the lesion from all directions. It enables us to give a larger amount of ray, by giving more skin surface to work on, and it appears to have a decidedly more powerful effect upon the lesions treated. The usual method of procedure is to divide all sides of the area to be treated into small fields of 25 to 30 sq. cm. and to treat each field in rotation.

Some men use two or even three tubes at the same time. Warnekros[4] describes a technique that he uses occasionally in the treatment of carcinoma of the uterus, where he places two tubes over the abdomen and one into the vagina, all working simultaneously.

On a recent visit to Berlin, I saw him use the double tube method, but cannot say that I was much impressed with the advantage of it. His main object to save time is defeated by the fact that the current cannot be turned on until both tubes are placed in position, and the vacuum of both tubes must be identical to have them working right. To regulate this takes time, so that whatever is saved by the combined exposure, is lost by the preliminaries.

3. *Massive doses.*—Up to a comparatively short time ago, the usual routine in *x*-ray therapy was to administer a fractional dose two or three times a week, until the patient received a certain amount, or until the first sign of a dermatitis developed. This was rather an unsatisfactory method as it was very difficult to estimate the amount of ray administered, and often the dermatitis became more severe than was anticipated, or the results were not satisfactory on account of the insufficient quantity of the ray given.

All this has been obviated by giving one carefully measured massive dose up to the degree of toleration, and then discontinuing treatment until the effect of this dose had worn off.

*Read at a meeting of the American Roentgen Ray Society, held at Cleveland in September, 1914.

The amount that can safely be administered in one treatment has increased a great deal with the use of the aluminum filters. Thus we find that by using a 3 mm. aluminum filter, and a ray of high penetration, 3 or 4 (or more) erythema doses can safely be administered without any danger of producing even a first degree dermatitis.

The amount generally administered at one sitting is about 15 to 20 X, measured under 13 mm. aluminum. This can be safely given once every three weeks, or under certain conditions oftener without any danger whatever.

The method I saw them use in abdominal malignant growths at Kroenig's clinic in Freiburg was to dissect the skin over the abdomen, stitch back the flaps, and pour in rays *ad libitum* over the dissected area. The amount that could be administered this way without producing any dermatitis is almost incredible.

I saw them give a patient with a uterine carcinoma, daily treatments for weeks, each treatment amounting to what would ordinarily measure up to at least 10 erythema doses, without any visible signs of injury. We also find that certain tissues possess a wonderful tolerance for almost any amount of *x*-rays without showing any injury. Thus, for instance, the mucous membrane of the vagina will tolerate any amount of hard filtered rays.

By carefully protecting the outside area, one can give through the vagina daily treatments, lasting for hours each time, continued indefinitely for weeks, without producing even the slightest dermatitis.

In fact, the only thing that seems to limit the amount of rays that can be given this way, is the time at the operator's disposal, and the length of time the patient can stand the discomfort of the position.

Warnekros[4] at Bumm's clinic in Berlin claims that by the use of a transformer manufactured by the Veifa-Werke, in connection with a water spray tube, so called "maximum tube," which gives a very large percentage of hard rays, he is enabled to increase greatly the amount of his dosage, over any skin area, without producing any injurious effect.

He administers over each area treated in eight succeeding days, an amount equal to about 350 X measured under 3 mm. of aluminum. At the end of this time a slight dermatitis develops which generally disappears in about one week, without giving the patient the slightest discomfort. I saw him use this tube and apparatus and was much impressed by the large quantity of ray that it produces.

In quality it did not seem to differ from the rays we got from the "Müller rapid," or the "penetrans tube," but evidently there must be a difference because no skin would tolerate the dosage from these tubes that he advocates to be given with the "Maximum tube."

I experimented with an American made spray tube, built on the same principle as the Maximum tube, but found that it did not possess any advantage over the "penetrans tube" whatever.

I might say a word about the method of measuring the dosage in deep therapy: We have no accurate means of measuring the dosage at present. All our methods are merely comparative. The one mostly used is by means of Kienbock strips placed upon the skin. We know that 10 X without a filter constitutes an erythema dose, and this has been our standard. But we find that by using 1, 2 or 3 mm. aluminum filters we can give the equivalent of 20, 30, 40, or even more X (as measured without a filter), without producing an erythema, so that if 10 X does not mean an erythema dose, and 20 X does not mean two erythema doses, then X has no real significance.

The ordinary Kienbock scale and strips as manufactured, cannot measure above 10 X. To obviate this, a scale has been devised by Gauss to measure higher dosages up to 25 X. This scale can be used only when the ray is measured under 13 mm. aluminum and the tube used is pumped to 9½ to 10 Wehnelt. With a lower tube the amount registered would be too small and with a higher tube too great.

In discussing this question with Kienbock I found that he disclaims all responsibility for the scale and considers it not very accurate.

Nevertheless it is probably at present the best method we have, although merely comparative, and answers the purpose of getting some idea as to the amount of ray given.

The solution of the problem will be to determine the amount of ray necessary to produce an erythema with 1, 2 or 3 mm. filter, and to construct scales on these standards.

4. *The Use of Rays of a certain Degree of Penetration.*—The degree of penetration that has been found probably most advantageous in deep therapy is from 8½ to 9 Bauer (12¾ to 13½ Wehnelt). Anything below this does not possess a sufficient quantity of hard rays to produce the best effects.

There seems to be a limit to the hardness of the ray that can be used to advantage in therapy. I think this is due to the fact that probably the most powerful therapeutic effects are produced by the rays which are absorbed by the tissues we aim to affect. So that extremely hard rays which penetrate the tissues very rapidly, and are absorbed by them but to a slight degree, will produce very little change in the tissues through which they travel.

This is purely an hypothesis, and probably is not endorsed by some of our best Roentgenologists, but nevertheless I have found in my experience that extremely hard rays which measure above the Bauer scale do not appear to possess much therapeutic value.

Although I have seen Kienbock work with tubes which he calls over-hardened tubes, which are so hard that sparks are continually playing around the tube and which cannot give more than 2 or 2½ Ma. even with the strongest current passed through them.

As to the results accomplished with deep therapy in the treatment of malignant growths, there is no question that they have been decidedly more satisfactory since we have adopted the technique which I previously described.

Despite the advances we have made in this subject, it still holds good that no operable cases of deep seated malignant growths should be treated with *x*-ray, except where patients refuse to be operated upon. The treatment is still reserved for inoperable cases, for recurrences, and for prophylactic treatments following operation.

The scope of this paper does not permit me to go into any detailed history of the cases I have treated. As a matter of fact, I do not think that detailed histories of cases cured, improved, etc., have any other than statistical value, for there seems to be some individual, intangible something which practically puts each case into a class by itself.

The result of fourteen years' work with Roentgen-therapy and the treatment of hundreds of cases of deep seated malignant growths, treated in hospital and private practice force me to the conclusion that there is some at present unrecognizable difference in apparently identical cases, which determines the degree to which they will respond to *x*-ray treatment. This difference is irrespective of microscopical findings, tissues involved, condition of patient, etc.—although it probably has some bearing upon the degree of malignancy that we cannot recognize at present. I am sure that most of you have come to similar conclusions. I have seen a case of recurrent adenocarcinoma of the uterus entirely disappear under treatment, where the next apparently identical case showed very little improvement under the same treatment.

I have seen a case of carcinoma, involving the left nares and antrum entirely disappear and remain well up to date (4½ years), where other similar cases did not respond.

A case of epithelioma of the tongue with glandular envolvement, is perfectly well to-day, almost five years after treatment, where other apparently identical conditions showed practically no response whatever.

One might go on and cite these cases indefinitely.

At any rate, while we sometimes get extremely satisfactory results in the treatment of deep seated malignant growths, we are still in no position to make definite promises at the beginning of treatment, as to the probable termination of any case.

The fact that we occasionally get brilliant results in the form of cures, very often improvement in symptoms, in the alleviation of pain and prolongation of life, I think is sufficient to justify our demand that all cases of inoperable and recurrent malignant growths should be given the benefit of this chance, before they are given up as absolutely hopeless.

Especially until the advances in medicine have produced something that offers more hope.

Combined Treatment.—Roentgen therapy in malignancy is very frequently combined with other allied methods of treatment, such as radium, mesothorium, etc. This is too wide a field for me to enter upon in this paper, besides it is only a short time ago that I published the results of my observations on this question.[5]

But I might mention a few words in connection with the combination of injections of various Colloidal metals with Roentgen therapy.

Probably the most important of these is the combination devised by Czerny and Werner at Heidelberg, under the name of "enzytol."

This is a combination of borate of cholin in connection with colloidal selenium and vanadium. It is given in the form of daily injections and is always given in combination with Roentgen-ray treatments. It makes the tissues much more susceptible to radioactive treatment, and in addition has the facility of absorbing the rays and carrying them through the circulation to the metastases.

The injections are given as follows: Begin with 2 c.c. of a 10 per cent. solution to 18 c.c. of a physiological saline solution. This is done for 2 or 3 days, when the dose is increased to 3 c.c. in 17 c.c. of saline solution. Three days later it is increased to 4 c.c. in 16 c.c. of saline solution.

This is continued daily for about three weeks, or until the patients complain of a great deal of weakness. It is then discontinued for three weeks and repeated again. Injections must be given very slowly. During the injections the patients suddenly develop symptoms of congestion, salivation, lacrymation, and nausea, but this only lasts from one-half to one minute. In carcinoma of the bladder the enzytol is injected through a catheter, 10 c.c. of a 10 per cent. solution to 50 c.c. of saline.

If veins cannot be found for intravenous injections, the solution may be injected into the gluteal muscles. For this purpose they use 4 to 5 c.c. of the 10 per cent. solution undiluted. In prophylactic treatments after operations, they also combine enzytol injections with roentgen ray.

They think that with the combined method their results are decidedly better, especially in malignant growths involving the digestive tract.

I have been using enzytol for the past few months, but my experience with it is entirely too limited to justify my drawing any conclusions.

Prophylactic Treatment.—The postoperative *x*-ray treatment of malignancy, with the object of reducing the chances of recurrences, is developing into one of the most important branches of deep Roentgen-therapy.

During the limited length of time, since it has been carefully and systematically carried out, it has been shown that it unquestionably diminishes the percentage of post operative recurrences.

It should be used in every case, following all operations for malignancy, no matter how radical and thorough the operation was, and how little chance there appears to be of recurrence.

No matter how carefully a surgeon operates, it is impossible for him to know that some small, almost invisible affected gland has not escaped his attention. It is these small foci which develop and are generally the source of future trouble.

We know the powerful effect the ray has upon glandular tissue, and we can readily understand how a thorough course of raying would help to keep the development of these glands in abeyance.

Prophylactic treatments to be efficient must be thorough, systematic, and persisted with for a period of at least three years. Perhaps the best routine is to begin treatment about 10 to 14 days after operation.

The first four series are given at intervals of four weeks, followed by treatments given every six weeks during the balance of the first year. The second year every eight weeks, and the third year every three months. The area to be irradiated is divided into small fields and each field is given about 15 X of hard, filtered rays, measured under 13 mm. of aluminum.

In carcinoma mammæ, we must be sure to include the entire surface, beginning laterally from the outer margin of the sternum to a line drawn with the outer border of the axilla, and longitudinally from the diaphragm up to and including the supraclavicular space.

Considering that the treatment is not accompanied by any danger whatever, and that the length of time between treatments is so long that it does not entail much hardship upon the patient, I feel that it is high time that the surgeon should be made to realize that his responsibility does not end with the operation and that he has been derelict in his duty in not advising his patients to have the operation followed by a course of prophylactic raying. They are most assuredly entitled to that additional chance.

Unfortunately, the average surgeon is a believer

in his knife only, and has but little faith in any other method of treatment. He operates again and again on a patient and will only relinquish them for other methods of treatment when they have reached the final stages of their illness. This is a grave error; there is no doubt whatever that if these patients were referred to us shortly after operation we would be in a position to do a great deal more for them.

QUINSY OR PERITONSILLAR ABSCESS.

BY E. HARRISON GRIFFIN, M.D.
NEW YORK.

THE term quinsy has been used to designate an affection of the throat attending an acute inflammatory condition of the tissues surrounding the tonsils and at times the tonsils themselves, when they are present, as there are throats affected with quinsy in which the tonsil may be absolutely negative. This inflammatory condition persists generally until suppuration takes place, and the abscess is either opened by the surgeon's knife to the great relief of the sufferer; or allowed by ignorance or mismanagement and great suffering on the part of the patient to progress to the point where nature takes the place of the scalpel and opens the abscess. The throat may become almost entirely closed by the presence of a quinsy and the breathing space almost entirely obliterated and the patient struggles to obtain enough air to sustain life. There have been a number of deaths by strangulation caused by this disease. Years ago, before this disease was studied with the nicety that it is to-day, the French advocated and performed tracheotomy during an attack. This was the usual procedure as the cause and the internal opening by the knife had not been mastered.

The term quinsy is rather an indefinite term and does not describe the condition as perfectly as the term peritonsillitis, which signifies an inflammation of the tissues around the tonsils. A cellulitis of the tissues of the fauces. About 95 per cent. of these cases will give a history of rheumatism in some form or other, a rheumatism of the joints, or muscles, or a chronic pain in the throat, or a history of huskiness of voice, the symptoms pointing to a chronic rheumatism of the fauces awaiting only some slight cause to start up an acute attack of this complaint. In about 5 per cent. of cases the rheumatic history is absent and only the throat condition is present. One attack of quinsy renders the patient prone to future attacks. It is the exception and not the rule for the patient to be free from this disorder after he has had his initial attack. I have seen a patient have four peritonsillar abscesses in the course of three months. When one attack supervenes so quickly upon another the first attack has never been thoroughly cured, only patched up, so to speak. The following case illustrates this fact:

CASE I.—A patient, male, came under my care at the dispensary of the old Bellevue Hospital complaining of inability to swallow and to open the mouth, and when this was forcibly attempted a most excruciating pain occurred at the angle of the jaw on the affected side. Examination of the fauces showed this part congested and markedly swollen. Examination with the forefinger of the left hand showed a point of softness and fluctuation. The temperature of the patient was 103.5° F. The abscess was opened at the above point and a large jet of pus followed the knife. The patient was put under the routine treatment that I will describe later and told to apply on the following clinic day. I did not see the patient for a month, when he again came under my care in the same condition as at the first visit. The abscess was again opened and the pus again freely discharged. The patient said that he had never been so well as between the two attacks, having had nothing pointing to a throat manifestation until the so-called second quinsy. The patient remained well for over a month, when he again applied with a sore throat. An examination showed a third attack of quinsy. The abscess was again opened. The history between the several attacks was negative. A short time later he again applied with a sore throat. The red congestion, the swollen membrane, and the pain at the angle of the jaw suggested only one diagnosis: return of the quinsy. The abscess was again opened and probed as at the former operations. The patient was scolded and impressed with the fact that he must come regularly for treatment to prevent future attacks of this ailment. Each day the abscess was probed and a weak solution of tincture of iodine was introduced into the wound by means of a little absorbent cotton on a probe. The wound was treated like any common abscess; it was treated until it healed from the bottom. The surface wound was kept open until the sinus had thoroughly drained; then the part was allowed to close. This was the end of the attacks of peritonsillitis.

I believe, as I have stated before, that when one quinsy follows another after a short period this is due to the fact that the first quinsy or abscess has never been thoroughly eradicated. It is like leaving in the abdomen a diseased appendix and expecting a perfect cure. One who has never probed a quinsy abscess would be surprised at the extent and depth to which the pus may burrow in one of these attacks. The mere lancing and the getting out of a large stream of pus does not always signify the end. It is only when the sinus is thoroughly cleansed and the parts have granulated from the bottom that the omega of the disease has been reached.

An attack of peritonsillitis generally starts with a distinct chill and is followed by a rise of temperature as high as 103° or over. The patient complains of pain in the back, headache, and pain in all the bones; in fact, the initial symptoms suggest an acute attack of articular rheumatism. The throat symptoms quickly follow; a swelling of the membrane of the fauces, the difficulty in swallowing, pain at the angle of the jaw, and a difficulty in opening the mouth. The latter symptom is an important diagnostic sign of quinsy. Excluding tetanus I know of no other disease that gives this diagnostic symptom. In croupous tonsollitis, follicular tonsillitis, and diphtheria the mouth can be opened wide, but in the average attack of quinsy there is always a restriction in opening the mouth due to the inflammation at the angle of the jaw and the beginning of pus at this location. I have seen the teeth so closed that I have only been able to introduce a knife with the blade turned parallel with the tongue when I wished to evacuate the pus. This point I emphasized to my students in my nose and throat lectures at Bellevue and I taught my class to diagnose this complaint by the restricted way in which the patient opened his mouth. The mouth is so closed at times that an examination is obtained only

by a great deal of tact and patience on the part of the physician. The average locality for the beginning of pus is at a point on the palate designated by an imaginary line drawn from the anterior pillar of the fauces to the corresponding pillar on the other side, the line crossing at the top of the uvula. Pus, if present, will generally be found in the location midway between the uvula and the anterior pillar. This is true of about 80 per cent. of the cases. In other cases the pus may be found at any point in the tissue inflamed. I have found pus higher up on the palate, and have had to make another incision deeper into the involved tissue. The part should be thoroughly palpated by the finger, if possible, before operation, in an effort to find where the quinsy points. The patient can often help the physician in this respect. I operated on a physician who localized exactly the site of the pus. I put my knife in the part he designated after I had satisfied myself by my finger that he was right and was gratified to see pus shoot out in a large stream. In a case where the location of pus is in question, the patient's feeling must often help the solution.

Peritonsilitis can be divided into two distinct types: the rheumatic peritonsillitis, and the gouty tonsillitis. They both start with the same symptoms and to all appearances look alike, only the latter or gouty tonsillitis is not amenable to the same treatment as the former. I have made the division and will later illustrate the cases.

Rheumatic peritonsillitis generally ends in suppuration with a discharge of pus obtained either by the surgeon's knife or by nature while the gouty peritonsillitis remains and persists as a hard, swollen mass in the throat; with difficulty in opening the mouth and the tardy formation of pus. Generally the pus element is absent; only the extreme pain and the swollen fauces designate the disease. These cases baffled my endeavors for years until I happily made the above division; and in grouping my cases under this nomenclature I have been able to render greater service to my patients. Previous to this grouping while regarding quinsy under one head I had cases I easily aborted; others that underwent quick suppuration and were terminated by operation; and others that resisted all treatment and seemed to drag on an existence for days and weeks with absolutely no progress tending to suppuration or a mitigation of the symptoms. There was only a hard mass under the finger. There was no point designating suppuration, and for days there occurred no change pointing to an abatement of the symptoms. If the case does not end in suppuration in a few days after the initial chill and the subsequent fever, and the mass feels hard and unwieldy under the touch, the diagnosis of gouty peritonsillitis can be made and the treatment can be given for this condition. Quinsy is no discriminator as to age. I have seen it in a baby of two months and in an old man of eighty, both with initial attacks.

I have seen one attack of quinsy follow another year in and year out until the throat membrane had had a thorough treatment and the patient's system had undergone thorough medication. Then these yearly attacks have stopped and the patient has been free from his yearly quinsy. It is always wise to start in with a five-grain dose of calomel followed six hours afterward by a large saline purgative. A ten-grain dose of quinine may be given with benefit with the calomel. If this does not abort the quinsy we have to deal with the stage of suppuration. This is hastened by allowing the patient to steam his throat continuously with the aid of the kettles that are common on the market.

I remember making an early call on a Christmas morning upon an old patient of mine who had her yearly quinsy. She was leaning on one side of the bed suffering all the agony that is heralded in with this complaint. I treated her throat, gave her a few directions, and departed. When I called again in the afternoon I was able to find where the quinsy pointed. I passed in my knife and liberated a large amount of pus. The relief was instantaneous. Her faced changed in an instant, although the pus was streaming from her throat. I then turned to my patient and wished her "A Merry Christmas." I told her I did not have the heart to wish her one when I called in the morning. One who has handled these cases can easily understand this picture.

The bowels should be kept well open during an attack and a nightly does of ten grains of quinine should be given either in pill form, if the patient is able to swallow, or in a liquid solution, if the patient cannot take a pill. Ten grains of salicylate of sodium can be given every three hours in plenty of water. Scarifying the surface of the inflammation with a small bistoury by causing the escape of blood often gives relief before the pus has formed. The throat should be examined upon each visit with the aid of a strong light. The fingers should be used in each examination to detect the early formation of pus. Time should be taken in this examination and pus should be liberated as early as possible, for the comfort of the patient. The parts can be cocainized by the local application of a 10 to 20 per cent. solution of this drug rubbed over the surface of the membrane by a piece of cotton fastened to a probe. The operation is painless and the relief is beyond description. The worst case of quinsy I think I ever treated was the following:

Case II.—A woman applied at the Bellevue Dispensary for treatment. She had seen a physician previous to this visit who had diagnosed her condition as hypertrophy of the tonsils. He had operated and removed part of the tonsil. When she applied for treatment it was with a great difficulty that she could breathe. Her mouth was tightly clinched and I was only able to introduce a knife between her set teeth and grope in the dark for the site of the pus. I was able at last to strike it. The pus flowed out in abundance and the patient left the clinic able to open her mouth wide and able to eat a meal, the first for a week. An operation on the tonsils under these conditions was positively not indicated and might have led to serious results. There had evidently been a mistaken diagnosis.

Case III.—Some years ago a patient, male, age about forty, of a plethoric constitution, weight about two hundred pounds, came under my care with quinsy sore throat. He gave a history of having these attacks ever since his twenty-fifth year. He was hardly able to open his mouth and was breathing with difficulty. An examination of his throat showed the parts red and congested and very hard to the touch. I placed him under the routine treatment and ordered the steam kettle for his throat. Each day I sought some point where there might be pus. I scarified and opened the parts at several points. The blood-letting gave him temporary relief, but I was unable to strike pus. I kept the points open by passing in a large blunt uterine sound.

This condition lasted for over two weeks; nothing seemed to dissipate the hardness of the mass or to produce a flow of pus. It was nearly three weeks before the mass began to soften and disappear without any pus production. I treated this case for about five attacks of this nature, each attack running through the same course. His suffering was intense. The only procedure that gave him any relief was to cut deep into the mass and let out as much blood as possible. This was was an

actor and once I brought him through an engagement in New York, seeing him twice and three times a day; at each visit letting out as much blood by the knife as was feasible. I had opened deep into the mass and was able to pass my uterine sound deep into the interior. I had several of these openings in the hope that I could find some pus and hasten the termination of his acute suffering. These attacks generally came on about October or November after his summer vacation. He told me once that he knew he was going to have a hard season with his throat as he had taken very little exercise that summer and had mostly lolled around on a veranda. He had gained over twenty-five pounds in weight, eaten hugely, and was afraid the next thing he would have would be the gout. I had exhausted almost the whole pharmacopeia in trying to find him a remedy that would give him some relief. His last attack was very severe and protracted. I had opened the mass at several points, but there seemed to be nothing that would give him any relief. After he had left my office I thought of his remarks and decided to prescribe for him the wine of colchicum seeds, twenty drops in a glass of water every three hours. This I did at the evening visit. This was on a Saturday. Sunday he had to leave to play in Toronto. I made an appointment with him at my office for five in the morning, so he could catch a train for that point. When he rang the bell the next morning I opened the door and saw my friend and patient muffled up in a large coat and in a teeming snow storm. The first words he greeted me with were, "Doctor, I am well! That last medicine worked like magic." The medicine was pushed for a few days and did what no other drug accomplished. It softened the mass and produced a normal throat.

Case IV.—Some years ago I was called to see this patient in consultation at the Hospital for Deformities and Joint Diseases. The patient was a well-developed woman, who gave a history of quinsy. She had been ill for over a week. The quinsy had been opened thoroughly and properly; still she was unable to take food or leave her bed. She had been running a temperature of about 103°. With difficulty I passed my finger into her mouth, trying to feel if there was any point where pus might be present. The whole part was one large, hard mass; there was absolutely no point where pus might be hidden. I prescribed a purgative, to be followed by a saline in the morning, and twenty drops of wine of colchicum every three hours in water. Upon my visit the next day I found my patient sitting up in bed. The fever had disappeared and she was able to open her mouth to the normal extent. The following day she called at my office to receive treatment. My first visit was on a Friday, my second on a Saturday, when she was out of bed and well, and Sunday the patient was at my office. This result in this type of quinsy I attributed to the diagnosis of gouty peritonsillitis.

These two cases are only two of hundreds in which I have used this drug with most gratifying results.

In treating quinsy one should not be satisfied with a single method. One should go into the history of the case, find out how many attacks the patient has had, and make a differential diagnosis between rheumatic and gouty peritonsillitis. One should find the site of the pus and open the abscess as soon as possible and keep the part open until the wound granulates from the bottom. The cavity should be washed out with a small syringe with a 25 per cent. solution of argyrol (which is better than iodine), and this should be continued till the wound has granulated. If this is done the patient will be less liable to a return of his quinsy. After an attack the patient should be placed under proper medication to prevent the yearly return of the affection. His urine should be examined in every case. Albumin is generally present during an attack but disappears after convalescence. Don't be satisfied with the statement that the patient has had his yearly quinsy for ten or twenty years and that his father before him had his quinsy. Look out for the cause and correct it.

Block of Brooklyn finds an hereditary factor in separation, desertion, and divorce, and states that these run through families. I believe this is so; but the cause of quinsy can be found and the hereditary proclivities eliminated if the disease is individually studied, and if the patient follows systematically a prescribed treatment for this very painful and, in some cases, dangerous ailment.

55 West Forty-seventh Street.

PITUITARY EXTRACT IN UTERINE BLEEDING.

PRELIMINARY REPORT OF CASES.

By ADOLPH JACOBY, M.D.,

NEW YORK.

CLINICAL ASSISTANT GYNECOLOGIST, NEW YORK POST GRADUATE MEDICAL SCHOOL HOSPITAL.

Uterine bleeding shall be used in this article to include menorrhagia or excessive bleeding at the menstrual period, and metrorhagia or irregular bleeding between menstrual periods. We shall not here enter into a detailed account of all the causes which may produce bleeding, but shall simply enumerate those most frequently met with.

Among these are severe anemia in young girls, hemophilia, and occasionally cardiac disease. A frequent cause of both menorrhagia and metrorrhagia is an overgrown endometrium, a hyperplasia of the uterine lining, which later in life may develop into carcinoma. Other causes are polypi of the uterus and inflammation of the endometrium. Then there are those conditions of the uterine wall, such as fibrosis uteri, large fibroids of the uterus, especially the submucous variety, subinvolution, and carcinoma, which diminish the contractile power of the uterine muscle and blood-vessels. Retroversion, causing an increased congestion, occasionally causes excessive menstrual flow.

Inflammatory conditions outside of the uterus, such as inflammation of the tubes and ovaries, inflammations of the perimetrium and the parametrium, are very often the cause of excessive bleeding due to the increased congestion which they produce. Another condition which is often accompanied by irregular bleeding is that following vaginal operations in which the uterus is fixed or suspended to the anterior vaginal wall. Threatened abortion and retention of portions of the placenta or membranes cause uterine bleeding, but will not be considered here.

The conditions as above enumerated are those most commonly met with as causative factors of uterine bleeding. Theoretically we may consider excessive uterine bleeding to result from an increase in the stimulating agent, which causes the normal menstrual flow. This stimulating agent is found in the internal secretion produced by the ovaries, which normally causes a congestion of the uterine lining and moderate flow of blood every 28 days. When this secretion is in excess, the congestion produced is increased and there is a corresponding increase in the loss of blood from the uterus. If, in addition, the uterus is already diseased by conditions which increase the vascularity of the lining or diminish the contractility of the uterine wall or blood-vessels, the effect of the increased stimulus furnished by the ovaries will be greatly enhanced and cause a far greater loss of blood from the uterus.

The nonoperative treatment of this condition has heretofore been confined chiefly to the administra-

	Menstrual History	Diagnosis	Number of Injections	Result	Next Menstruation	
					Interval	Duration
1.	Vaginal fixation 6 months ago, bleeding irregularly since	Vaginal fixation	10	Stopped after 8 injections	4 weeks	5 days
2.	Menstruation every 2 weeks—profuse	Bilateral salpingitis	10	Menstruated 7 days during injections	3 weeks	7 days

15.	Irregular—bleeding for 3 months	Vaginal fixation	7	Bleeding considerably diminished	Patient lost sight of	

tion of drugs such as ergot, stypticin, chloride of calcium, digitalis, hydrastis, persulphate of iron, and local applications of carbolic acid, zinc sulphate, perchloride of iron, combined with hot douches. These measures were all directed to the diminution of local congestion, or destruction of an endometrium of increased vascularity, or an attempt to increase the contractility of the uterus and the coagulability of the blood, but in no way influenced the causative agent, namely, the increased ovarian secretion.

We know from our experience with pituitary extract in labor cases, that the hypodermic injection of this extract has a selective action upon the uterine muscle, causing it to contract very powerfully. We are also led to believe that the secretion of the pituitary gland acts in direct antithesis to the ovarian secretion. From this it would be reasonable to expect that the administration of the extract of the pituitary gland, in such cases where there is an increased ovarian secretion or diminished uterine contractility, causing an increased flow of blood from the uterus would have the effect of causing a marked diminution in the amount of blood lost. This is splendidly borne out by the results obtained in actual practice.

The method of using pituitary extract is extremely simple. It is furnished ready for hypodermic use in one c.c. sealed glass ampoules, by various chemical concerns under a variety of trade names. The dose used is usually 1 c.c. given hypodermically into the subcutaneous tissues of the arm over the deltoid muscle. This dose is equivalent to 3 grains of the fresh gland or 1 grain of the extract of the fresh gland. The dose is repeated every other day, using alternate arms, until 10 doses are given. This is usually found to be sufficient. Further doses may be given if necessary. In the majority of cases effects are obtained with fewer doses.

In all the cases in which the injections have been used there were no infections, and very few symptoms subsequent to the injection. Several patients complained of cramps in the lower abdomen, and occasionally nausea. One patient complained of vomiting and diarrhea, which disappeared upon diminution of the dose. There was no instance of any severe constitutional disturbance.

Among the conditions in which the injections were used were, anemia causing menorrhagia in a virgin, threatened abortion, hypertrophy of the endometrium, fibrosis uteri, fibroids, subinvolution, retroversion, disease of the adnexa, parametritis, and certain cases following vaginal operation in which the uterus had been fixed to the anterior vaginal wall.

A brief description of the cases and results subsequent to the injections may be more readily seen in the accompanying table.

The results obtained have been very encouraging, and in our series uniformly successful in alleviating the condition for which they were given. In every case of menorrhagia, the duration and the amount of the menstrual flow have been diminished. In cases of metrorrhagia the duration and the amount of bleeding have been diminished, and the intervals between bleedings have been lengthened to more nearly the normal. In cases of continual bleeding following operation, the bleeding ceased, and the normal menstrual cycle was restored. In the one case in which it was used for threatened abortion, the bleeding stopped. However, more extensive experience will be necessary before it is advisable to use injections in all cases of threatened abortion.

From these results it will be seen that we have a very valuable remedy in pituitary extract administered hypodermically for this class of cases. Further experience will be necessary to determine all the conditions in which the pituitary extract acts successfully; nevertheless, it is certainly well worth trying before giving up medical means, and resorting to operative interference.

1141 Fox Street.

THE PREVENTION, THE TREATMENT, AND THE CURE OF TUBERCULOSIS.

By OWEN PAGET, M.D.,

FREMANTLE, W. AUSTRALIA.

MEDICAL OFFICER OF HEALTH, FREMANTLE AND DISTRICT.

It may seem an unjustifiable temerity to use the above title for what is at best an essay. This paper is, however, intended as a forerunner of a new outlook on tuberculosis, and incidentally as an introduction to fresh perceptions in physiology and pathology.

Space compels that matters proved merely to my satisfaction be cited as if accepted facts. Desultory papers published in the *Australian Medical Gazette* have superficially dealt with some of these

problems. The establishment of others on a firm basis is dependent on time and a more general observation.

In a country such as this, where one of the main industries is gold-mining, facilities exist for the study of miner's phthisis. This in its pure form, probably very rare, is a fibrosis of the lung, produced by the irritation of more or less aseptic mineral rock dust.

Since economically this is a serious disease, and in South Africa helped to bring about a revolution, it is natural to ask whether it can be prevented. Common sense suggests the simple expedient of breathing through the nose.

Now it is easy, by examining men engaged for thirty years or more in mining, or men immersed in an atmosphere of dust with their mouths covered, to demonstrate that dust, except in the too roomy nose, is deposited only in the anterior fleshy cartilaginous part. Further, it is blown out even more easily than it is drawn in. It is hard to believe that numerous commissions have been held over the subject of miner's phthisis without result. The exposition of the above simple physiological action has been actually ridiculed, even by medical men.

Assuming that breathing through the nose will prevent a pure fibrosis of the lung, it is natural to ask why fibrosis of the lung exists; because the instinct of protection against disease is inherent. It is necessary here to use statements, the value of which can be fully discussed on some other occasion.

(1) About 80 per cent. of Australian English adults are mouth-breathers. Of these the majority can only with difficulty breathe through the nose for any length of time.

(2) This occurrence can be traced to wrong methods of feeding in infancy, a subject dealt with by Sir Arbuthnot Lane some fifteen years ago in the *Lancet*, and by myself latterly in the *Australian Medical Gazette*.

(3) About 95 per cent. of mouth-breathers can be converted into nose-breathers by the use of silver props inserted into the anterior cartilaginous part of the nose. This may be denied by nose specialists, but is easily demonstrated by any practitioner.

It is justifiable to presume that a disease can be prevented by the restriction of a physiological function. The subject of a theoretical miner's phthisis, *i.e.* a pure fibrosis, is discussed in order to advance an argument step by step. Usually speaking, miner's phthisis is a combination of fibrosis with an infective disorder, generally tuberculosis.

The sunbeam discloses that the air of the drawing room in like manner to that of the street contains dust. Such dust can for reasoning purposes be divided into: (a) mechanical particles, (b) bacterial elements.

It has already been shown that mechanical particles are caught by the cartilaginous part of the nose; when they pass too far they are rejected by sneezing. Probably very few microbes are checked in the anterior part of the nose, as the current is too strong. The surfaces, except that of the septum, are unsuitable, too, for the deposition of such minute particles. A study of the middle nose, *i.e.* that portion situated between the anterior and posterior choanæ, together with its attendant sinuses, discloses the fact that the inspiratory air current is altered in direction and character, as compared with the cartilaginous portion.

Professor Ballenger describes the inspiratory current as passing along the upper parts, *i.e.* in the region of the superior and middle turbinates.

The process is, however, more complicated than supposed. The circulation of air in the sinuses can be proved, both experimentally and otherwise. In reality the original swift current of air is changed into slowing, flowing whirls; while the intricacy of the process is such as to bring a maximum amount of air into contact with the membrane covering the turbinates, and that lining the sinuses. In some animals this mechanism is very beautifully arranged.

Now if it is true that the air and its contained microbes are brought into intimate contact with the cells covering the turbinates and lining of the sinuses, a natural interest is aroused as to the effect produced by the cells on the microbes, or vice versa. Reference on this subject should be made to the bacteriology of the sinuses as given in Professor Skillern's book. Briefly expressed, these structures have apparently bactericidal powers.

In addition there is the following statement by the Professor: "Empyema of any of the sinuses, purely and solely the result of infection from the tubercle bacillus, must be an extremely rare affection, for to my knowledge no case has occurred in the Rush Hospital for Consumptives since its foundation in 1895."

Elsewhere is stated that tuberculosis of the sinuses is practically an unknown disease.

That of two organs, the lungs and the middle nose, both exposed to the same contaminating influence, *viz.*, the air, one should be most often attacked by tuberculosis and the other practically never, is surely a striking phenomenon.

A study of the air currents of the middle nose leads to the belief that the microbes contained in the inspired air will be deposited on its surface. A review of the bacteriology discloses the probability of such microbes being destroyed.

If the nose is capable of removing mechanical particles from the inspired air, and also of catching and destroying some of the contained microbes, to what extent is this of assistance in protecting us from disease? It is necessary to confine attention to the human in whom the physiological capacity of the nose is probably less than among wild animals; while the demands on this guardian are increased by the nature of civilization, entailing as it does towns, trains, and trams. As a frequent sufferer and in my capacity as a medical officer of health, a local disease called "influenza" had interested me for many years. Believing that this disease was dust borne, it was easy to experiment on myself by means of nasal props. After a time I discovered that while formerly almost weekly attacked, it was now apparently impossible for me to be infected. Now the irregularity of my use of the props, the character of my nasal obstruction, and the fact that through forgetfulness one often breathed through the mouth seemed to show that the process was not one of bactericidal action only. It appeared rather as if through breathing a certain number of the infecting microbes into the nose it was possible to neutralize the harmful effects of the remainder breathed through the mouth. In other words, it was seemingly a simple affair to establish a condition of natural immunity. If the nose was competent to filter off mechanical particles, to destroy bacteria, and to confer immunity, it was plainly interesting to investigate its capacities, once disease was acquired.

For this purpose tuberculosis was selected, and the two following types of experiments made:

(1) Patients with incipient tuberculosis were advised, after props had been inserted into the nose and a proper current of air established, to sniff up commercial dried tubercle bacillary substance into the nostrils. This substance was expensive, and for such experiments the dose 0.01 of a milligram was too small. However, it was possible to observe beneficial effects.

(2) In advanced cases the direction was to dry the sputum in the sun (in this country usually very bright and hot), or else to dry the sputum in an oven, short of burning. The dried product was scraped off the tin or glass and then powdered. A pinch was sniffed up into alternate nostrils four times a day like snuff. The results were so striking as to lead me to formulate the following hypothesis:

"It is reasonable to suggest that advanced pulmonary tuberculosis can be cured in six weeks." This hypothesis led me into so many definitions of words and meanings that I have determined to alter it to read as follows:

"It is reasonable to suggest that advanced pulmonary tuberculosis can be markedly benefited within six weeks. Complete cure can be expected within six months, the following being accepted as criteria of such a state: (1) Absence of sputum and tubercle bacilli. (2) Disappearance of symptoms of the disease and return to normal or approximately normal weight. (3) Absence of all physical signs of active disease. Cavities of course remain cavities. Existing fibrosis is not benefited. By an advanced case is meant such a case as would under ordinary circumstances have three or more months to live.

The technique of this treatment is as follows:

(1) It is essential that a proper inspiratory current of air be established through the nose. This can be done, as already stated, by means of silver props, or a small operation which I have planned and practised. That the props are of suitable size and shape is shown by the patient even in advanced phthisis, stating that he can breathe through the nose. More important still, when taking the snuff he should feel that it goes up into the roof of the nose between the eyebrows and not into the back of the throat. The action in the region of the inferior turbinate is probably very slight in comparison with that in the sinuses and region of the superior and middle turbinates.

(2) The circulation of the air through the nose should be established for about a week before the inhalation of the sputum through the nose commences.

(3) The sputum is dried on a sheet of glass or tin in a bright sun, or in an oven short of scorching. Theoretically it should not matter whether the bacilli are alive or dead. Practically, however, it is important that the sputum be sterilized by heat short of burning, since there is a danger of overdosage, and it is much safer for attendants. No chemical or disinfectants should be added to it.

(4) This sputum film on the glass is scraped off into a jar and powdered as finely as possible. This is done so that it may the more easily reach the neighborhood of the superior and middle turbinates, where apparently the best effects are produced.

(5) In early cases, or cases with little sputum, lycopodium powder is added, well stirred round with the sputum, dried, and sterilized as above. With only one spit a day it is possible to make an adequate supply of snuff by stirring sufficient saline solution or water with the lycopodium.

(6) In cases with temperatures running 100° or under a pinch of the powder is taken between the forefinger and thumb exactly as snuff is taken and sniffed into one nostril, so that it is felt to reach the roof of the nose, *i.e.* between the eyebrows. This is done four times a day. Right nostril 8 A.M. and 4 P.M. Left nostril 12 M. and 8 P.M.

(7) In hectic cases with temperatures 101° to 103°, the same treatment. In these cases there is a feeling of malaise produced. The treatment can be pushed to every three hours, but in cases with high temperatures this should be done cautiously. The indications that the nose is being worked beyond its capacity are (a) the dry nose, (b) the snotty nose, or purulent coryza. The purulent coryza is usually preceded by a watery flow, but may come on very suddenly. Either the dry or purulent nose is an indication for immediately stopping the treatment for two or three days at least. The watery nose is a sign for careful watching.

What benefits may be expected from this treatment, and what dangers guarded against?

In cases with temperatures below 100° there is within the first week or two an almost invariable improvement in appetite, diminution of sputum, and increased capacity for exertion. There is, however, usually a loss of weight from one to four pounds. This is later on more than made up, and is not cause for alarm. Improvement goes on gradually, temperature becomes normal, physical signs lessen, sputum becomes less purulent and more mucoid, and in six weeks' time the patient is obviously on the road to recovery. In six months' time there should be no signs of active disease, though such cavities and fibrosis as exist at the commencement of the treatment naturally remain.

No beneficial result from the treatment is an expression of faulty technique. The commonest cause is to have a nose of such a character that the inspiratory current flows along the inferior turbinate and thence into the back of the throat. In such cases a different prop should be used. It may even be necessary to use an insufflator, but I do not recommend it.

In cases with temperatures of 101° to 103° the results are somewhat different. With an administration of snuff two or three times a day only small or even no effect may be produced. One naturally pushes the treatment up to, say, every three hours. There may then result a crisis as in pneumonia. This, though beneficial, is serious and the patient may even die by heart failure.

Even in mild cases the organ which requires watching is the heart. It would take too much space to discuss this matter fully, but a skillful physician is required in all cases, and he will find close attention to the heart of more value than examinations of the lungs. All cases over 100° are treated as cases of fever. There is no stuffing with milk or food, and the bowels are regulated to act daily. Appetite becomes natural with the general improvement, and should not be forced.

Vomiting seems to be an expression of abdominal tuberculosis, though not evident on palpation. It is an indication to push the treatment.

It is natural to ask whether this reaction produced by the nose is confined to the lungs. Apparently not, since it is possible to influence beneficially

tuberculous bone disease in this way. However, my data are at the present moment not sufficient to enable me to speak authoritatively.

By the courtesy of Dr. Robertson, Principal Medical Officer of the State of Victoria, the value of these propositions is being tested by Dr. Herlitz. A series of cases will shortly be started here under the auspices of the British Medical Association at one of the Government sanatoria. Now, though it is right that original experiments should be made on derelict cases, it is obvious that if my theories are correct no such cases will arise in the future.

Viewing the subject from the standpoint of a physician of preventive medicine instead of that of the clinical physician, it is possible to demonstrate that: (1) Tuberculosis can be physiologically prevented. (2) There exists a natural physiological immunity. (3) The disease by an artificial physiological appeal is probably easily curable in its early stages in two or six weeks. Lastly, let our minds take a wider range. Assuming that it is possible for a tuberculous patient to be benefited by sniffing his own sputum into his nose, it is plain that a physiological protection exists in our bodies against disease.

Leucocytosis is a pathological process and is in my opinion *le dernier resort* of a body, whose physiological processes have broken down or are naturally inefficient. Such an idea is not isolated. Sir Arbuthnot Lane in his operative work on the colon arrives at identical conclusions. It can, in fact, be argued with reason that abdominal tuberculosis is analagous to pulmonary tuberculosis, in that it is due to physiological inefficiency. It is possible to treat the lung through the intestine, but results are not so definite as through the nose. The fundamental principles governing these perceptions were evidently appreciated by Sir James Paget in his lecture on blood-poisoning delivered in 1871.

It would be unwise, however, to bring forward any theories at this stage. The genuineness of my experiments must be established on a firm basis.

SPLENECTOMY FOR PERNICIOUS ANEMIA; APPARENT RECOVERY; DEATH.

By J. F. BALDWIN, M.D.,

COLUMBUS, O.

SURGEON TO GRANT HOSPITAL, ETC.

So much has been written of late in regard to the treatment of pernicious anemia by splenectomy, that it seems important that every case, whether successful or the reverse, should be placed on record; hence the following report:

Miss E. S., aged 34, patient of Dr. J. M. Thomas, Columbus, Ohio, was operated upon by me April 22, 1914, for pernicious anemia. The diagnosis had been established by the progress of the disease and repeated blood examinations. The spleen was materially enlarged. The operation was made in the usual way, occupied but a few minutes of time, and the patient's operative recovery was absolutely smooth. Her blood examination four days before her operation showed hemoglobin, 30 per cent.; reds, 1,616,000; color index 1; leucocytes, 5,400; polynuclears, 65 per cent. Six days after her operation the hemoglobin was 22 per cent.; red cells, 1,632,000; color index, 1; leucocytes, 12,000; polynuclears, 64 per cent.; small lymphocytes, 30 per cent.; large lymphocytes, 5 per cent.; eosinophiles, 1 per cent. June 14, hemoglobin, 30 per cent.; reds, 1,208,000; color index, 1.7; leucocytes, 18,000; polynuclears, 83.6 per cent.; small lymphocytes, 12 per cent.; large lymphocytes, 4.4 per cent. From this time on her improvement was very rapid, and on June 23 her blood count showed hemoglobin, 68 per cent.; red cells, 3,319,000; color index, 1; leucocytes, 6,400; polynuclears, 69 per cent.; small lymphocytes, 25 per cent.; large, 4 per cent.; eosinophiles, 2 per cent. At this time the patient left the city to visit friends. She returned in July, and her physician reported that on her return he found that she was in bad shape; had gone all to pieces. The disease made rapid progress and she died July 29. A specimen of her blood was obtained a few hours before her death, and while she was comatose. This showed hemoglobin, 12 per cent.; red cells, 720,000; color index, 1.4; leucocytes, 37,000; polynuclears, 87 per cent.; small lymphocytes, 9.2 per cent.; large, 3.4 per cent.; eosinophiles, 0.4 per cent.

Any surgeon who is contemplating splenectomy for pernicious anemia should read the article by Moffett on the subject of this form of anemia as it appears in the *American Journal of the Medical Sciences* of December, 1914.

Medicolegal Notes.

Malpractice—Insufficient Evidence.—In an action for malpractice consisting of the alleged improper treatment of the plaintiff so as to necessitate the removal of her uterus, it appeared that the plaintiff commenced to flow excessively; that the defendant was called; that he told the plaintiff's husband that the plaintiff was going to have a miscarriage; that he could not call that night as he was about to make another call, but he gave him some medicine for her to take and said he would call the next morning. The defendant testified that the medicine he gave for the plaintiff to stop the flowing was ergot, which the undisputed evidence showed was a proper remedy and was effective. He further testified that when he called the next morning he sterilized his instruments, dilated the vagina with a speculum, removed from it all the blood clots, some of which were dark and resembled pieces of liver, with a curette, and tamponed the vagina with antiseptic wool tampons, which he pressed against and around the mouth of the uterus with a pair of dressing forceps; that none of these instruments penetrated the uterus; that he took nothing but the blood clots from the vagina, and that the whole treatment occupied not more than twenty minutes. He further testified that on the following morning he removed the tampons, washed out the vagina with an antiseptic solution and tamponed it again; that he told the plaintiff and her husband that he considered her condition serious and that it might be necessary to have an operation performed; that he was not a surgeon and advised them to consult a surgeon, and that Dr. Otis was agreed upon; whereupon Dr. Otis came and made a diagnosis. He announced that the plaintiff was suffering from a rupture of the uterus, and she was taken to a hospital and the uterus removed. The undisputed evidence in the case was that when Dr. Otis performed the operation he found a rupture of the fundus of the uterus at a spot where there had been a chronic degeneration thereof; that the degeneration had proceeded to such an extent that when he attempted to sew the ruptured parts together the tissues would not hold the stitches, and he was compelled to remove the uterus entirely; that no pieces of flesh had been torn from the uterus; that it showed no evidence of laceration or bruising, or of having been abused by the insertion of instruments; that the uterus itself was preserved by the plaintiff, introduced on the trial and corroborated the above facts; that the rupture found in the degenerated portion of the fundus of the uterus was sufficient to have caused the excessive flowing; that this degenerated condition was sufficient to have caused the rupture therein; that the excessive flowing took place before the defendant did any of the acts complained of. It was held that fair consideration of the above facts could lead to but one conclusion, viz., the excessive flowing was caused by a rupture of the uterus; the rupture of the uterus was caused by the chronic degenerated condition thereof; and that such chronic degenerated condition of the uterus was the cause of the necessity for its removal, and not anything the defendant might have done. It was therefore held that the defendant was not responsible for the removal of the uterus, and judgment for the plaintiff was reversed. —Barton v. Southwick, 185 Ill. App. 24.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery

New York, February 6, 1915.

ANTIVACCINATION IN DISGUISE.

A BILL has been introduced into the Assembly of New York State repealing the law requiring vaccination as a preliminary to the admission of children to the public schools. The present law provides that "no child or person not vaccinated shall be admitted or received into any of the public schools of the State" and it enjoins the trustees or other managers having the charge of such schools to see that this provision of the law is enforced. The proposed amendment does away with this section, substituting therefor a provision that unvaccinated children shall be excluded from the schools only when "smallpox exists in any school district or city, or in the vicinity thereof, and the State commissioner of health or the local board of health shall certify in writing to the school authorities" that the disease is present. In other words, it shall be the duty of the watchman to lock the stable door only after the horse is stolen.

Truly the ingenuity of the antivaccinationists would be admirable were it exerted in a more worthy cause. Here is a bill which would disarm criticism by admitting in principle the value of vaccination while at the same time, under cover of this apparent support of the procedure, it aims to do away entirely with the practice, for, of course, it is to be regarded only as an entering wedge. In a few years, if no epidemic of smallpox appears, as probably none will, the community still being well protected, the antivaccinationists will call for the repeal of the law and will point to the fact that there has been no smallpox even though there has been no compulsory vaccination of school children. And so a generation will arise of unvaccinated persons supplying fuel for a devastating epidemic in the future.

It is useless to rehearse all the irrefutable arguments in support of the protective value of vaccination; those who can be convinced are already in favor of the procedure, and by those who are so dull that they cannot follow a logical argument, the clearest presentation of the subject would not be understood. But there are some who may be misled by this apparent approval of vaccination who should be warned against giving the bill their support. Vaccination being a preventive measure, it is evidently the height of folly to postpone it until a smallpox epidemic breaks out instead of resorting to it to prevent such an epidemic. Prevention is better than cure and it is better to avert an epidemic than to let it get started and then fight it. And who will take the responsibility for the deaths of the nonvaccinated school-children who fall victims to the epidemic before the machinery can be started which will confer upon the survivors the security which should have been theirs from the beginning? The bill should meet an early death.

THE RENAISSANCE OF ACONITE.

ACONITE is one of the drugs which found greater favor in the eyes of earlier clinicians than it does to-day. Probably its indiscriminate use in as many febrile conditions caused the pendulum to swing in the direction of the almost absolute neglect of this valuable therapeutic agent. But aconite is again coming into its own. There is no other drug which can approach it as an efficient means of reducing high arterial blood pressure. This is a conclusion which has been reached by many observers and which should be widely recognized by the medical profession.

In the presence of a case of cerebral hemorrhage the most urgent need as a rule is the reduction of a high blood pressure. Frederick Tilney in "The Modern Treatment of Nervous and Mental Diseases" reports the results of his experiments undertaken to determine the relative value of various agents used as cardiovascular depressants. He found in the first place that the hypodermic injection of distilled water causes a decided rise of blood pressure. Aconitine is an active hypodermic agent for reducing blood pressure, but its effects are not always uniform and its commercial preparations are not always reliable. Gelseminine hydrochlorate in doses of 1 25 grain acts as a mild depressant, but its primary depressant effect is followed by a slight rise, with a subsequent secondary decline which tends to be more persistent. In view of the blood pressure raising action of distilled water, the point is emphasized that aqueous hypodermic solutions for depressant effects must be as highly concentrated as possible.

If the victim of cerebral hemorrhage is able to swallow it is preferable to administer drugs by the mouth. Of all the cardiovascular depressants Tilney finds aconite the most reliable, and recommends the use of the tincture in doses of five minims. If the initial dose has produced no effect upon the blood pressure, the dose should be repeated at the end of an hour. If the blood pressure is 200 mm. or over an initial dose of ten minims may be given. But pressure readings should be taken every half hour. The drug may be continued for several hours until the desired depressant effect is reached. The administration should be discontinued if there arise symptoms of intoxication, as dilatation of the pupil, vomiting, irregularity of the pulse, cold moist skin, an erythematous rash, and dyspnea. As regards the question as to what constitutes a sufficient decrease of the blood pressure, the answer is given that a fall of 20 to 30 mm. may be deemed sufficient, and that when the initial pressure is well above 200 mm., the aim should be to bring it down below the 200 mm. mark.

An eloquent plea for the more general use of aconite as a vasodilator is made by William Hanna Thomson (*American Journal of the Medical Sciences*, January, 1915). The use of the nitrites is condemned on the ground of their transient effects. Aconite is regarded as the most efficient vasodilator available, but it must be given in full doses of ten to fifteen drops of the 10 per cent. tincture. In cases of interstitial nephritis the most important action of aconite is to increase the elimination of urea. Aconite is of particular value in the melancholic symptoms associated with high blood pressure.

THE SPREAD OF TUBERCULOSIS.

ALTHOUGH it is generally recognized that the spread of tuberculosis has been halted, there are many who are sceptical concerning the extremely optimistic reports which proceed from certain quarters. In any event, it is well to regard the matter from an unprejudiced standpoint and to weigh the pros and cons in an impartial manner. In *Public Health Reports*, January 8, 1915, is a report by Dr. H. G. Lampson on the spread of infection in certain tuberculous families in five counties in Minnesota. The plan of work projected and carried out was thorough, but owing to lack of space the details of the scheme followed must be omitted. The striking features of the investigation were the high percentage of positive tuberculin reactions among apparently healthy people, who had been definitely exposed to infection continuously and for a considerable period of time; the much lower percentage of positive reactions among those exposed less continuously, and for shorter periods; and the absence, practically, of positive reactions among those in whom, from the history, the exposure was deemed doubtful. The total amount of material was small, which will detract to some extent from the value of the investigation but, on the other hand, as the writer points out, the uniformity of the results in the different geographical locations should give some weight to the findings.

The conclusions reached were as follows: (1) A very large percentage, 79 per cent., of the individuals fully exposed for a long period to open cases of tuberculosis became infected. (2) A much smaller percentage, 28 per cent., of those partially exposed or exposed for a short period of time became infected. (3) The percentage of infections from casual exposure, such as everyone encounters, was small, 8 per cent. (4) The more frequent infection of children may be explained, at least in part, by their more intimate contact with the patient. (5) At all ages the intimacy and length of exposure are the determining factors in infection with tuberculosis.

The moral to be drawn from the results of the investigations referred to would appear to be that open cases of tuberculosis should be segregated. Undoubtedly, the prevention of the spread of tuberculosis rests mainly on the adoption of two measures—prompt diagnosis and efficient treatment of incipient tuberculosis, and the isolation of open cases unless conditions are such that all danger from them can be obviated.

FLOODING WITH ANTITOXIN IN THE TREATMENT OF TETANUS.

SURGEONS have doubtless been looking forward with hope to a consensus of opinion on the treatment of tetanus, as a consequence of the experiences of the present war. The ideal has been throughout a synergism between specific and symptomatic treatment. Serum has often been too scarce for full therapeutic dosage, and when we bear in mind (from analogy with laboratory tetanus) that much larger quantities ought to be given than have thus far been prescribed, it follows that the power of serum over the developed disease has never been fully tested. In regard to symptomatic treatment, magnesium sulphate seems to be growing constantly into favor.

In the military supplement of the *Münchener medizinische Wochenschrift* for December 22 we find a paper by Dreyfus and Unger which is more satisfactory throughout than any other based upon recent war experience. They have given nearly 4,000 units of antitoxin in individual cases, the initial dose having been as high at times as 600 units. There were but two cases of anaphylaxis, neither serious. Of 32 men tested, 22 recovered. One case, a mild one which recovered, is omitted as not suitable for analysis. Sixteen cases had an incubation period of from 10 to 24 days and all recovered but one. The fifteen severe cases were of extreme, often foudroyant type, with incubation period of from six to nine days. Of this series six were saved, the mortality being 60 per cent. No foudroyant case was saved, and the five patients, doomed from the start, represent the residual and inevitable mortality. If these are omitted from the statistics the mortality of severe and medium cases was about 20 per cent. In addition, two of the deaths were not directly due to the convulsions, as both were improving at the time. Both men died of respiratory complications. A third patient, not severely ill, was not admitted until too late for antitoxin, and did not respond to treatment. It must be emphasized that flooding with serum was practised only in the severer cases. Others were also dosed according to severity. Magnesium was given in large doses by both intraspinal and intramuscular injection—in some cases until threatening symptoms appeared. Smaller doses were, however, found to possess the same efficiency. Magnesium is to be pushed alone when it can be shown to decrease the convulsions; otherwise it may be combined with morphine.

A TAX IN RESTRAINT OF HEALTH.

THE necessity of good teeth for good health was recognized many years ago, but it is only recently that the close causal relation between dental caries, root abscess, and pyorrhea on the one side and rheumatic disorders, serious cardiac disease, and high blood pressure on the other has been clearly demonstrated. Now, however, the fact is firmly established and no one would attempt to treat certain forms of infection without first making an inquiry into the condition of the teeth and their sockets, and if these are found diseased the first therapeutic endeavors are directed against them. And

furthermore, as the present-day medical science is advancing steadily in the line of prevention, the necessity of proper care of the mouth and teeth is being more and more insisted upon. In view of this it is greatly to be regretted that Congress, in decreeing the present war tax, should have penalized the use of dentifrices by imposing a tax upon tooth pastes, powders, and washes. While the amount placed upon these necessities is not large, it is nevertheless sufficient, in the case of a large family with a small and precarious income, to determine against their use, for the tax, like the freight, is always paid by the consumer and not by the producer. We are glad to know, therefore, that a petition is to be presented to Congress by a committee of physicians and dentists of New York and by various health organizations of the country to abate this unwise impost; and we would suggest that the success of the movement would be assured if every physician and dentist in the country were to write at once to his Congressman, calling his attention to this petition, and asking his support in repealing the tax on these articles so indispensable to the preservation of health.

The Treatment and Prevention of Pellagra.

Although the cause of pellagra has not yet been definitely decided, the large majority of American observers hold to the old view that it is of dietary origin. Drs. Joseph Goldberger, U. S. Public Health Service, and surgeon in charge of Pellagra Investigations, C. H. Waring, assistant surgeon, and David G. Willets, technical assistant, in *Public Health Reports*, Oct. 23, 1914, point out that the general tenor of their studies has led them to conclude: (1) That pellagra is not a communicable, an infectious, or a contagious disease, but that it is essentially of dietary origin. (2) That it is dependent on some yet undetermined fault in a diet in which the animal or leguminous protein component is disproportionately small and the non-leguminous vegetable component disproportionately large. (3) That no pellagra develops in those who consume a mixed, well-balanced, and varied diet, such, for example, as that furnished by the Government to the enlisted men of the Army, Navy, and Marine Corps. Such being the deductions of these investigators, it follows that in treating pellagra the question of diet is the first consideration. Regarding pellagra then as a fault of nutrition, "mal de misère," or as chronic intoxication, the authors recommend that as long as clinical evidences of pellagra are manifest the patient should be given and urged to take an abundance of fresh milk, eggs, fresh lean meat, beans, and fresh and dried (not canned) peas. No medicine has any specific value. Thus the prevention and eradication of pellagra will depend essentially on the substitution of a mixed, well-balanced, varied diet for the restricted, one-sided diet that the individual will be found to have consumed prior to the development of symptoms.

Eradicating the Plague.

The work of eradicating plague in whatever part of the United States it may be found is proceeding energetically at the hands of members of the United States Public Health Service. In *Public Health Reports*, January 8, 1915, Passed Asst.-Surg. Huxley reports the plague eradicative work in California, for the week ended December 12, 1914. Surgeon Corput in a report regarding the work in New Orleans, states that chronic plague was determined in a rat found December 16, 1914, in a suburban slaughterhouse; also he reports the discovery of other plague-infected rats in various parts of the city. Surgeon Lloyd reports on plague-eradicative work at Seattle, Washington, as does Surgeon Trotter in Hawaii. The work done already by the United States Public Health Service in fighting the plague has redounded to its credit and has increased the confidence felt in the Service by the general public and medical profession of America. There is now little fear that plague will ever gain a foothold on this continent.

News of the Week.

For the Relief of Belgian Physicians.—The Committee of American Physicians for the Aid of the Belgian Profession is constantly receiving heart-rending reports regarding the distress of our Belgian colleagues and their families. Their plight is indeed a sad one. The urgency of the situation resembles that of a great conflagration. Promptness of action doubles and trebles its value. February will be a hard month in Belgium, with great suffering from severe weather added to their other trials. Our English colleagues are fully awake to the situation. Though their number is small compared to that of America, they have contributed several thousand pounds to this cause. Arrangements have been perfected by which contributions are being promptly converted into supplies with every assurance that they will reach our destitute colleagues. Two hundred boxes of food have been purchased during the week ending January 30. The following contributions were received during the week:

Drs. C. H. and W. J. Mayo, Rochester, Minn.	$100
Miss Margaret E. Reed, Chicago, Ill.	1
Dr. E. L. Neff, Pittsburgh, Pa.	5
Dr. F. P. Sprague, Boston, Mass.	50
Dr. Caspar W. Miller, Wallingford, Pa.	50
Dr. John T. Bottomley, Boston, Mass.	25
Dr. Henry W. Frauenthal, New York, N. Y.	25
Dr. Edwin Sternberger, New York, N. Y.	10
Capt. W. A. Powell, M. C., U. S. A., Nogales, Ariz.	5
Dr. Frederick Fraley, Philadelphia, Pa.	10
Dr. George W. Ely, Pittsburgh, Pa.	5
Dr. Samuel C. Plummer, Chicago, Ill.	5
Dr. R. W. Hodges, Ralic, Mich.	10
Dr. Ellen A. Stone, Providence, R. I.	10
Dr. Charles A. Elsberg, New York, N. Y.	25
Dr. F. M. Hicks, San Antonio, Tex.	10
Dr. Marion Marsh, Worcester, Mass.	2
Ohio Valley Academy of Medicine, Bellevue, Pa.	25
Dr. M. P. Messinger, Oakfield, N. Y.	2
Total	$375
Previously reported receipts.	1,791
Grand total	$2,166
Previously reported disbursements	$1,650
Disbursements week ending Jan. 30.	440
Total disbursements	$2,090
Balance	$76

F. F. SIMPSON, M.D.,
Treasurer.

Belgian Professors for Harvard.—The Harvard University corporation has set aside $100,000 to aid Belgian professors who have been driven from their land by warfare. Two of the faculty of Louvain University will come to Cambridge at the beginning of the next college year to take charge of courses at Harvard, and they will be paid for their work from this special fund.

Dr. Percy Turnure of the French Hospital in New York has sailed to take charge of an American hospital in France. He will be followed shortly by a staff of twenty-five surgeons and nurses.

Mortality Among French Surgeons.—*Le Caducée*, the journal of the French army medical corps, pub-

lishes a long list of casualties among the army surgeons, the losses being greater, it says, than in any of the other armies at war. The reason given for this is that the French surgeons never abandon their wounded, and when the main body falls back they are exposed to the enemy's fire or are taken prisoners. There are now 158 French army surgeons imprisoned in Germany.

Typhus in Vienna.—A dispatch from Berne, Switzerland, states that typhus fever is epidemic in Vienna, 363 cases having been reported in the ten days ending January 26.

Foot and Mouth Disease in Germany.—The *New York Times* publishes a letter stating that the food supply of Germany is seriously threatened by the widespread prevalence of the foot and mouth disease. Dr. Kirstein of the Bacteriological Institute of Berlin claims to have discovered that the pathogenic agent is a protozoon. If this is correct the disease will probably yield to emetine.

The New Kitasato Institute.—Prof. Dr. S. Kitasato of Japan, organizer of the Imperial Japanese Institute for the Study of Infectious Diseases and head of that institution since 1892, has resigned his position and organized a new institute of his own. He believed that the original research work was hampered by certain red tape, and that an ideal institute should be established, independent of all such drawbacks. All of his former associates and colleagues, including Dr. K. Shiga, discoverer of the bacillus of dysentery, and Dr. S. Hata, who shared the honors with Prof. Ehrlich in the invention of salvarsan, have also resigned with him to join the new institute. Dr. Kitasato has contributed all his personal estate to the institute, and his friends have raised sufficient funds for its permanent support.

Physicians' Mutual Aid Association.—The forty-sixth annual meeting of this association was held at the New York Academy of Medicine on January 19. Among the prominent items in the president's annual report were that the membership was close to 2,400 physicians; that the principal fund was almost $90,000; that there were forty-five death claims, and that the average age at death was sixty-two years. The youngest member was thirty-five years at death, the oldest was eighty-six. The purpose of the association is to provide an insurance of $1,000, to loan to sick members, and to provide a farm, if possible, in Dutchess or Monroe County for infirm and indigent members of the association. A reserve fund of $4,000, as required by the State Insurance Department, is set apart for that purpose. The following officers were elected for 1915: *President*, Dr. W. F. Mittendorf; *First Vice-President*, Dr. W. C. Phillips; *Second Vice-President*, Dr. J. W. Ingalls; *Recording Secretary*, Dr. A. Edward Davis; *Assistant Secretary*, Edward S. Peck; *Corresponding Secretary*, Dr. Ward B. Hoag; *Treasurer*, Dr. J. Bentley Squier; *Directors*, Drs. Godfrey R. Pisek, H. J. Boldt, and J. S. Waterman.

"The Woman's Medical Journal" announces that its issue for March will be an "internal secretion" number, containing articles on "Hypothyroidism," by Dr. Eugene Hertoghe of Antwerp, Belgium; "The Mamma as an Internal Secretory Organ," by Dr. Henry B. Hanover; "Rest as a Therapeutic Measure in Systemic Goiter," by Dr. Mary Sutton Macy, and the "Internal Secretion of the Ovary," by Dr. William Seaman Bainbridge.

The Death Rate in New York.—During the week ending January 23, the death rate in this city was 13.10 per thousand of the population as against 14.60 for the corresponding week last year. The decrease is equivalent to a saving of 171 lives. Deaths from influenza were the same as for the same week in 1914; deaths from heart disease, diseases of the digestive system, pulmonary tuberculosis, Bright's disease and nephritis were considerably less. More people died from pneumonia than in the corresponding week of 1914, but less than during the week ended January 16, 1915.

The Federation of State Medical Boards will hold its third annual meeting in Chicago on February 17, having a joint session with the Association of American Medical Colleges. Papers will be presented by President J. H. Finley, on "Some Thoughts on the Work of the State Board of Medical Examiners;" Dr. Henry S. Pritchett, President of the Carnegie Foundation, on "Classification of Medical Colleges;" Dr. Major J. Seelig of St. Louis, on "Fallacies in the Argument Against Full-time Clinical Instructors;" and Dr. W. P. Harlow and J. L. Heffron, on "Minimum Expense of Maintenance of an Acceptable Medical College." The president of the Federation is Dr. Charles H. Cook of Natick, Mass., the secretary Dr. Otto V. Huffman, secretary of the New York State Board, Albany.

Harvey Society.—The eighth lecture of this course will be given at the New York Academy of Medicine on February 13 at 8:30 P. M. by Dr. John A. Fordyce, on "Some Problems in the Pathology of Syphilis."

Hospital News.—Announcement is made that work will soon be begun on a new wing of the University Hospital at Charlottesville, Va. This addition, which will cost $50,000, will greatly increase the usefulness of the hospital.

The Baptist Sanatorium and Hospital at Houston, Texas, was formally opened to the public on Tuesday, January 19. The hospital is a seven-story concrete building with accommodations for 150 patients besides a baby camp on the roof where 50 children can be cared for.

Charitable Bequests.—By the will of the late Elizabeth A. Lippe of Philadelphia bequests are made as follows: Women's Homeopathic Hospital, $5,000, as an endowment in honor of Dr. Adolph Lippe; St. Joseph's Hospital, Reading, Pa., $5,000, for the endowment of a bed in memory of Theresa Eichorn Lippe; Children's Homeopathic Hospital of Philadelphia, $5,000, as an endowment in memory of Elizabeth Fiske Belknap; St. Vincent's Home and Maternity Hospital, $300.

The will of Mrs. Eliza McMillan creates a provisional trust fund for the founding of a hospital at Washington University. The fund, exceeding $1,000,000, is contingent on Mrs. McMillan's son, dying childless. He is now about 45 years old and has been long married.

By decision of the Orphans' Court of Philadelphia a bequest of $50,000 contained in the will of the late James F. Hope of that city is awarded to the Philadelphia Hospital for the Treatment of Contagious Diseases. According to the will of the testator, the sum named was devised "to any hospital in Philadelphia which shall be devoted to the treatment of contagious diseases, for the purpose of endowing a ward therein to be called the Hope Memorial Ward, and in case there should be no such hospital in the city at the time of my death or no hospital which will accept such a legacy on these terms, I agree then to give the said fund to the Episcopal Hospital. Eleven

hospitals made claim to the bequest, but the court decided that the only hospital in Philadelphia for the treatment of all contagious diseases is the Philadelphia Hospital for the Treatment of Contagious Diseases, popularly known as the Municipal Hospital.

By the will of the late Mrs. Helen Louise Merrick of Philadelphia the sum of $10,000 is bequeathed to the new children's ward of the Germantown Dispensary and Hospital, to St. Timothy's Hospital at Roxborough and to the Cosmopolitan Hospital of Giudecca, Venice.

The New Hampshire Memorial Hospital for Women and Children in Concord is named as beneficiary of a $5,000 bequest in the will of the late Helen E. Robinson. The bequest is for the furnishing, equipping, and maintenance of a free bed.

By the will of the late Francis Way Smith of Philadelphia, the sum og $98,000 is bequeathed to the Children's Seaside Home for Invalid Children at Atlantic City.

The Sale of Patent Medicines in New York City.—The Department of Health has adopted the regulation regarding the sale of proprietary or patent medicines in this city. No proprietary or patent medicine manufactured, prepared, or intended for internal human use, shall be held, offered for sale, sold or given away, in the City of New York, until the following requirements shall, in each instance, have been met:

The names of the ingredients of every such medicine shall be registered in the Department of Health. The expression "proprietary or patent medicine," for the purpose of this section shall be taken to mean and include every medicine or medicinal compound, manufactured, prepared, or intended, for internal human use, the name, composition, or definition of which is not to be found in the United States Pharmacopœia or National Formulary, or which does not bear the name of each ingredient conspicuously, clearly, and legibly set forth, in English, on the outside of each bottle, box, or package in which the said medicine or medicinal compound is held, offered for sale, sold, or given away. The provisions of this section shall not, however, apply to any medicine or medicinal compound, sold or given away upon the written prescription of a duly licensed physician, provided such medicine or medicinal compound be sold or given away to or for the use of the person for whom it shall have been prescribed, and provided, also, that the said prescription shall have been filed at the establishment or place where such medicine or medicinal compound is sold or given away, in chronological order according to the date of the receipt of such prescription at such establishment or place. Every such prescription shall remain so filed for a period of five years. The names of the ingredients of proprietary and patent medicines, registered in accordance with the terms of this section, and all information relating thereto or connected therewith, shall be regarded as confidential, and shall not be open to inspection by the public or any person other than the official custodian of such records in the department of health, such persons as may be authorized by law to inspect such records, and those duly authorized to prosecute or enforce the Federal Statutes, the Laws of the State of New York, both criminal and civil, and the Ordinances of the City of New York, but only for the purpose of such prosecution or enforcement. This section shall take effect December 31, 1915.

Medical Society Elections.—The Pathological Society of Philadelphia, at a meeting held January 14, the following officers were elected for the ensuing year: *President*, Dr. M. Howard Fussell; *Vice-President*, Dr. A. E. Taylor; *Secretary* and *Treasurer*, Dr. O. H. Perry Pepper; *Recorder*, Dr. John A. Kolmer.

The Society of American Bacteriologists held its annual meeting in Philadelphia at the Laboratory of Hygiene, University of Pennsylvania, December 29, 30, and 31, 1914. The following officers were elected: *President*, Dr. D. H. Bergey; *Vice-President*, Dr. John Woinzirl; *Secretary-Treasurer*, Dr. A. Parker Hitchens; *Council*, Drs. K. F. Kellerman, W. A. Stocking, Jr., R. E. Buchanan, and H. J. Conn; *Delegate to the A. A. A. S.*, Dr. M. J. Rosenau. The next regular meeting of the society will be held in Urbana, Ills. The chairman of the local committee is Prof. H. A. Harding. A special meeting of the society will be held in San Francisco during the summer.

The Philadelphia County Medical Society, at its annual meeting held January 20, the following officers were elected for the ensuing year: *President*, Dr. E. E. Montgomery; *First Vice-President*, Dr. Seneca Egbert; *Secretary*, Dr. Wm. S. Wray; *Assistant Secretary*, Dr. Elmer H. Funk; *Treasurer*, Dr. Edwin A. Shumway; *Censor*, Dr. Judson Daland; *Directors*, Drs. Wm. S. Newcomet, J. Torrance Rugh, and Wm. E. Parke.

The Bedford County (Tenn.) Medical Society elected the following officers at a meeting held on December 19 at Shelbyville: *President*, Dr. W. T. Robinson; *Vice-President*, Dr. S. S. Moody; *Secretary and Treasurer*, Dr. F. B. Reagor; *Censor*, Dr. T. R. Ray; *Delegate to State Medical Association*, Dr. T. H. Woods; *Alternate*, Dr. R. E. Shelton.

The Memphis and Shelby County (Tenn.) Medical Society at its annual meeting in Memphis on December 15 elected the following officers: *President*, Dr. J. C. Ayres; *Vice-President*, Dr. W. C. Campbell; *Secretary*, Dr. J. L. Andrews.

The Williamson County (Tenn.) Medical Society elected the following officers at a meeting held December 22: *President*, Dr. Sam White; *Vice-President;* Dr. J. D. Smith; *Secretary*, Dr. K. S. Howlett; *Treasurer*, Dr. B. T. Nolen.

The Warren County (Ky.) Medical Society met at Bowling Green on December 9 and elected the following officers: *President*, Dr. Finis London of Woodburn; *First Vice-President*, Dr. Ernest Rau; *Second Vice-President*, Dr. Hal Neel; *Secretary and Treasurer*, Dr. Burnett W. Wright; *Delegate to the State Society*, Dr. B. S. Rutherford.

Obituary Notes.—Dr. Benjamin Sharp, formerly professor of invertebrate zoology at the University of Pennsylvania, who died at Morehead, N. C., on January 24, at the age of 56 years, was graduated in medicine from the University of Pennsylvania, Medical Department, in 1879. The following year he received the degree of Ph.D from the same university, and in 1883 was honored by the University of Wurzburg, where he had continued his scientific studies, for his thesis on "The Eyes of Molluscs." For many years he served as corresponding secretary of the Philadelphia Academy of Natural Sciences, and had made many expeditions for the collection of specimens, going with Peary to the Arctic regions on his first trip in 1891, and again in 1895, and to the Hawaiian Islands in 1893.

Dr. William Peyton Tucker of St. Joseph, Mo., a graduate of the Ensworth Medical College, St. Joseph, in 1893, died at Colorado Springs, on December 25, aged 45 years.

Dr. Aaron S. Miller died of apoplexy at Saegersville, Pa., on December 31 at the age of 75 years. He was graduated from the New York University Medical College in the class of 1862 and was a member of the Medical Society of the State of Pennsylvania and the Lehigh County Medical Society.

Dr. Harry Gates Bullard of St. Johnsbury, Vt., a graduate of the Dartmouth Medical College, Hanover, N. H., in 1891, died at his home on January 3, aged 48 years.

Dr. Fred Hamilton Weir of Portland, Ore., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1885, formerly a resident of New York City, and a member of the Oregon State Medical Association, the Portland City and County Medical Society, and the Pacific Coast Oto-Ophthalmological Society, died at his home, from tuberculosis, on January 2, aged 50 years.

Dr. Frank B. Stallsworth of Cuba, Ala., a graduate of the University of Alabama School of Medicine, Mobile, in 1899, died at his home, after a long illness, on January 2.

Dr. Clarence Eugene Gardner of Narragansett Pier, R. I., a graduate of the Medico-Chirurgical College of Philadelphia in 1901, died at his home, from cancer of the stomach, on January 5, aged 37 years.

Dr. Diedrich A. Brumond of St. Stephen, New Brunswick, Canada, a graduate of the Northwestern University Medical School, Chicago, in 1899, died suddenly in his office on January 1, aged 40 years.

Dr. Benjamin Ewell Keys of Fate, Texas, a graduate of the Medical Department of the University of Nashville, Tenn., in 1900, died at his home from pneumonia, after a short illness, on January 5, aged 50 years.

Dr. Winfield Scott Norcross of Auburn, Me., a graduate of the State University of Iowa, College of Homeopathy, Iowa City, in 1886, and a veteran of the Civil War, died at his home, after a long illness, on January 6, aged 70 years.

Dr. Sterling J. Gates of Cliff, N. M., a graduate of the Tulane University of Louisiana, School of Medicine, New Orleans, in 1895, and a member of the American Medical Association and the New Mexico and Grant County Medical Societies, died at his home on January 4, aged 44 years.

Dr. Nathaniel Morton Ransom of Somerville, Mass., a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1861, and a member of the Massachusetts Medical Society and the Middlesex District Medical Society, died at his home after a long illness on January 8, aged 84 years.

Dr. Charlotte W. Ford of Morristown, N. J., a graduate of the Women's Medical College of the New York Infirmary for Women and Children, New York, in 1873, died at her home on January 9.

Dr. Richard Runyan Rogers of Trenton, N. J., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1862, a former surrogate of Monroe County, and at one time a member of the New Jersey State Legislature, died at his home on January 14, aged 91 years.

Dr. Hercule Dansereau of Thibodaux, La., a graduate of the Albany Medical College, Albany, N. Y., in 1853, died at his home, after several weeks' illness, on January 2, aged 82 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE WAR—TYPHOID CASES, PREVENTIVE INOCULATION—HOME HOSPITAL FOR TYPHOID—COLLOID GOLD—NATIONAL INSURANCE REPORT—BELGIAN RELIEF FUND—CHOLERA BACILLI—DR. BASHFORD—OBITUARY.

London, January 16, 1915.

The war, the wounded, the Army Medical Service, and allied matters continue to monopolize our attention; they intrude into almost every conversation. The sanitary supervision and medical care of troops are freely discussed by the public as well as the profession and the doctor is often assailed by the demand to settle doubtful questions. The arrival of sick and wounded from the front has been met, as far as possible, by the hospitals and infirmaries throughout the kingdom, but the wards offered by these institutions have not been sufficient and it has been necessary to adapt and furnish other buildings. Some of these buildings can thus be used exclusively for infectious diseases and still more complete segregation is secured by the hut system.

The outbreak of typhoid was, of course, anticipated by all who had had experience as well as by those whose knowledge of military medical history was confined to the records of former campaigns. The reports of the number of cases that have occurred are very contradictory and estimates will be found of little use. But the Army Medical Department seems to be awake and earnestly promoting preventive inoculation.

A strong opposition, however, to this prevention is already being organized by that mischievous group of ignorant, self-conceited persons who call themselves "antivaccinationists" and appear to be always ready to denounce any proposal they are incompetent to judge of. Without experience, without training which would fit them to consider a problem, they will take up a prejudice and proclaim that as a solution. To everything else they are anti, and though the world be against them they will not acknowledge their own insignificance. As to their last outcry against inoculation they would deprive recruits of the chance of preventing an attack of typhoid rather than admit that their opinion may possibly be erroneous. Said one, "I know a man who died soon after inoculation." He got for a reply, "Well one must be under the average, considering the thousands that did not die soon after it and the millions who die without having undergone it. A patient died soon after having his hair cut, but no one thought that that slight operation was the cause of his death."

A home hospital was opened last month and is now in full working order for typhoid and other infectious cases brought from the front, though those occurring in the service at home are also to be admitted. The cost has been met, to a considerable extent, by the Red Cross Society and private subscriptions, but the War Office has to provide the deficiency, and the working expenses. About 150 cases can be accommodated in the hospital, but the management is also prepared to carry out the hut system for convalescents and other suspected carriers.

At the French Academy Messrs. Letulle and Mage

have given some account of forty cases of typhoid treated by intravenous injections of colloid gold. A feeling of cold is first produced, soon followed by fever, sweating, and some cyanosis of the extremities. This state is succeeded in a few minutes by a calm feeling and sleep. The pulse remains good. A fall of temperature occurs three hours or more later, but no collapse. No contraindication was recorded, though threatened perforation might be considered so; but as all the cases recovered the treatment was put forward by the authors as free from danger.

The Report of the Departmental Committee to inquire into the working of the National Insurance Act, so far as the supposed excessive claims for sickness, is a document of grave import to the profession. Practically admitting excess of expenditure on sickness benefit, the blame is laid on the doctors. Defects in the administration of societies are indeed admitted, but more is attributed to the "carelessness and inaccuracies of the medical profession," which is thus the ever-ready scapegoat. Supposing that here and there a doctor may have been rather lax in granting certificates or may have been imposed upon, that is no reason for condemning the whole profession, just to let off the lay authorities who put off from time to time the various reforms suggested. Many imperfections in the system ought to have been corrected long ago, and many improvements should have been instituted, especially one or two which had been proposed by the doctors and have only now been adopted by the departmental committee.

The British committee in aid of the Belgian medical victims of recent troubles is intended to cooperate with those working on your side for the same purpose. We have opened a subscription here and already contributions have been raised which have justified a sub-committee being appointed to examine and decide on applications in making grants to relieve temporarily some of the more urgent cases.

Dr. Freeman of the bacteriological department of St. Mary's Hospital has made an adventurous trip into Gallicia in order to obtain some special cultures of cholera bacilli. He has, I am informed, succeeded in his enterprise. Perhaps he will supply his cultures to the doctors where the epidemic is present, for one may very properly hope he will have no chance of testing the treatment in an outbreak in this country.

Dr. E. F. Bashford has resigned the office of superintendent of the cancer research committee of the two Royal colleges on account of ill health. He had held the post for eight years.

Surgeon-General Wm. Henry McNamara, C.M.G., M.D., has died suddenly in his sixty-ninth year. He was educated at Queen's College, Cork, and the Ledwich School of Medicine, Dublin. He took the M.D. of the Royal University in 1867 and entered the Army Medical Service the same year. He was in the Egyptian Expedition of 1882, taking part in the battle of Tel-el-Kebir. As P. M. O. of the British Brigade he was in the Nile Expedition of 1898, being mentioned in despatches. In the South African War he was awarded the Queen's and the King's medals. He was created C.M.G. in 1900 and retired in 1906.

Dr. Henry Billinghurst of Midhurst died on the eighth instant, having reached the age of ninety-two.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

MILITARY SURGERY AND MEDICINE—WAR MEDICAL MEETINGS—BULLET AND SHELL WOUNDS—THE GERMAN AND FRENCH FIRST-AID PACKETS COMPARED—MASTISOL AND IODINE—FRENCH RIFLE WOUNDS MORE SEVERE THAN THE GERMAN—EXPECTANT TREATMENT OF ABDOMINAL WOUNDS—WOUNDS OF NERVOUS SYSTEM—SURGICAL EMPHYSEMA—DIMINISHING MORTALITY FROM TETANUS—AN EFFICIENT TREATMENT OF TETANUS—THE AIRMAN'S DART.

BERLIN, DECEMBER 15, 1914.

THE surgery of war and the diseases incident to war comprise the principal themes of present-day medical discussions. Medical journals are replete with articles inspired by the novel experiences of the physicians at the front and in the base and home hospitals. Evenings devoted to military medicine have been inaugurated by the medical societies. Moreover the men at the front have organized and have held meetings for the exchange of ideas. For example, such meetings have been held opposite the main French lines at Chauny, Peronne, and Pont Faverge. Naturally there has arisen an immense amount of material for medical discussion. Some of the most important observations may here be alluded to.

As regards bullet and shell wounds, it may be stated as a general proposition that the ultimate fate of the wounds is largely dependent upon the first dressing. For the purpose of the latter the German first-aid packet has been admirable. The disadvantage of the French packet is that it is sewed together and hence opened with difficulty by some of the wounded. Another disadvantage is that when the kit is once opened the contents are scattered. Upon the back where the fixation of our own packet cannot be absolutely assured, the packet is fastened with adhesive plaster or mastisol (a solution of mastic in benzol). As regards the surgical use of mastisol there is as yet no unanimity of opinion. Nevertheless those who are employing it are increasing in number. Nor is there any unanimity regarding the use of iodine. This is used a good deal in the German army but it is mostly regarded as superfluous.

In general, wounds from firearms at a distance have not been relatively very numerous. Unfortunately the French rifle has inflicted more irregular wounds than the German weapon, because it is longer than the latter and has a more slender point. The splintering and laceration produced by the French rifle are therefore more pronounced. Naturally the worst wounds are those inflicted by shrapnel. The fractures so frequently produced by bullets and shrapnel are to be treated with the aid of splints. The ideal procedure would be the use of plaster of Paris, but this is available only exceptionally at the first dressing. Amputations are rarely performed. When necessary they should be performed rapidly and in the most simple manner, and any possible improvement in the operation should be reserved for the after treatment.

The benign effect of the modern rifle-bullet is seen particularly in the case of wounds of the thorax. In most instances such wounds heal readily, a possibility not dreamed of in former days. Of greater difficulty is the question as to how to deal with wounds of the abdomen. The majority of reporters on this subject regard it as a closed

book. Operation can be considered in those cases only if it is feasible soon after the wound has been inflicted and if asepsis can be secured. Since these conditions usually cannot be fulfilled, bullet-wounds of the abdomen are as a rule let alone. In fact a series of cases have been reported in which healing occurred provided that absolute rest of the patient could be secured. Worthy of mention is the suggestion made that a special section of the dressing-station be set apart for abdominal operations. It is doubtful whether the suggestion is of any practical value.

Wounds involving the nervous system have been very common and among them principally the tangential wounds of the skull are there in which the surgical activities of the field hospital have been called into play. In the case of these wounds many excellent results have been obtained. The operation consists in enlarging the wound in the soft parts, removal of the splinters of bone, and aspiration of the softened masses of brain tissue. Prolapsed parts of the brain are removed, the bony border is made smooth, and the wound is drained.

While, on the one hand, erysipelas is rare, on the other hand surgical emphysema is quite common. In the latter condition the amputation of the wounded member is the only procedure of any value. Injections of oxygen are said to be of aid. A disease which we have had an opportunity to observe only rarely during times of peace, but which has arisen with frightful frequency during the present war, namely tetanus, was regarded at the beginning of the war with some uncertainty as to its proper management. Even though antitoxic serum and other remedies were available, there was lacking sufficient experience as to their proper use. It appears, however, as if during the later months of the war, the mortality from tetanus has dropped. In the beginning the death-rate was not less than 60 per cent., but this is now 35 per cent. and even less. The therapeutic measures have included subcutaneous, intravenous, and intraspinous injections of serum, the use of carbolic acid, magnesium sulphate, and narcotics; the employment of hot baths, and the application of the ultraviolet rays. One of the plans of treatment followed by the lowest mortality consisted of the following measures: With the onset of the first symptoms of tetanus 100 units of antitetanic serum are injected in the neighborhood of the wound. Two subcutaneous injections of magnesium sulphate are made daily. Every evening the patient is given a hot bath of 40° C. for twenty minutes. After the bath the patient is exposed to the ultraviolet rays for five minutes at a distance of 50 centimeters. On the second day the exposure is for ten minutes, on the third day for fifteen minutes, and on the fourth day for twenty minutes, and at a distance of 75 centimeters. The radiation is prolonged to one-half hour for each half of the body. If there are seven tetanic spasms 2 grams of chloral hydrate are administered every evening.

The use of the aeroplane has led to the discovery by the French of a new weapon, the airman's dart, a steel rod 12 centimeters long, the lower third of which is massive, and which tapers to a fine point. The upper two-thirds have their substance so diminished by four canals, that the arrow, no matter how it is thrown, always falls with its point downwards. Since the dart is thrown from a great height it acquires considerable velocity and effectiveness as a weapon. It has in some instances riveted the soldier to the ground by passing clean through his boot and foot. Although the wounds produced by this new weapon cannot become very common, nevertheless they may be quite serious. An illustrative case is the following: A soldier was admitted with the history that a half hour previously he had felt a sudden sharp stab in the region of the right shoulder, after which he had experienced difficulty in breathing. Examination showed in the region of the right supraclavicular space a small round wound. There were dyspnea, light cyanosis, pain in the hepatic region, and abdominal rigidity. The general condition and the pulse got so bad that an operation could not be carried out. Death occurred at the end of 36 hours. The dart had penetrated the thorax and was located in the abdomen.

5. Diabetes and Surgery.—E. H. Risley groups the cases presenting this association into the following categories: (1) Cases in which glycosuria is caused by the surgical lesion. (2) Cases in which it causes the surgical condition. (3) Cases in which the two are independent and do not influence each other. (4) Cases in which glycosuria is a harmful factor and adds to the danger of the already present disease or injury. The following rules may be laid down in regard to operations on diabetics: A thorough examination of the urine must be made in every case, especially for the detection of acetone and diacetic acid. The total amount of ammonia must always be estimated. No operation except of the extremest emergency should be performed if there is one gram of ammonia excreted in 24 hours, until this has been reduced to the normal amount, .759 gram. An operation should be postponed should there be acetone or diacetic acid, even if the amount of ammonia is normal. Much albumin in the urine is a contra-indication to operation and even in small amounts is of bad prognostic import. Most of the major operations of surgery have been and can be performed with success on diabetics. The presence of glycosuria should never deter the surgeon from performing any operation of emergency. Other cases should not be operated upon in which acetone, diacetic acid, and ammonia cannot be reduced by preliminary treatment. A mortality of 20 to 30 per cent. is to be expected in this class of cases. The use of an anesthetic other than ether and chloroform, careful dietary treatment before operation, the prevention of sepsis, and rapid technique will still further reduce the mortality.

7. Recovery from Coccidioidal Granuloma.—S. B. Walbach emphasizes the fact that this condition is to be distinguished from cutaneous blastomycosis and the systemic infection sometimes produced by the organism of cutaneous blastomycosis. The author's case was that of a woman who for years had suffered from what were apparently furuncles, but which had the peculiarity that some did not discharge and others when opened yielded a thin, necrotic material, and healed slowly. W. P. Bolles operated upon two nodules on the fore-

head and one in the left axilla, opening and curetting them. The contents consisted of necrotic tissue with brownish or grayish pus, some granular bodies like miliary tubercles, and inflammatory thickening. Cultures obtained from the lesions and from inoculated rabbits showed the specific organisms. The patient recovered. This case represents one of the twenty-two cases of recoveries in this condition reported by McNeal and Taylor.

8. **Alcoholic Injection of the Superior Laryngeal Nerve.**—I. Sobotky states that the blocking of the internal laryngeal nerve, the internal branch of the superior laryngeal nerve, gives the greatest and most prominent relief to the sufferer from advanced tuberculosis of the larynx. The technique is as follows: Place the patient in a recumbent position. Using the usual aseptic precautions, locate by pressure the tender spot where the nerve pierces the thyrohyoid membrane, usually at the upper edge of the thyroid cartilage and one-third the distance from the outer edge. Introduce a somewhat blunted needle about one and a half centimeters into this point at right angles to the skin. Should the patient cough, the needle is in the lumen of the larynx and must be withdrawn. He must be forbidden to talk or to shout and told to signify ear pain by raising his hand. If the introduction of the needle has produced no discomfort, turn it upward and outward toward the ear, and if this does not produce intense pain move the needle cautiously in various directions until the pain, referred to the ear, is produced. The instant the patient shows he is in pain, push the piston of the syringe slowly and allow only one or two drops of the 85 per cent. solution of alcohol to escape. If this augments the pain inject one to one and a half c.c. In successful injections there is little inflammatory reaction about the site. The pain on swallowing disappears and does not return for anywhere from ten days to three months. If both right and left internal laryngeal nerves are to be injected, as is usually necessary, it is best to wait two or three days between injections.

9. Subacromial Bursitis. S. O. Fields.

1. **History of Medical Ethics.**—G. W. Cook, in tracing this history, notes that prior to the seventeenth century medical ethics, medical legislation, and forensic medicine were practically one subject. The code of Hammurabi contains a detailed schedule of medical fees. The Hippocratic oath is the oldest of its kind, the Vedic and Unani oaths being based upon it. The Visigoths held the physician to strict accountability, and while the penalties imposed were very drastic in character, the ordinances contain some protective clauses. In the medical law promulgated by Frederick the Second in 1240 it appears that the requirements for the practice of the healing art in the Middle Ages were of a high grade. The injunction of professional secrecy is contained in all codes of medical ethics.

2. **The Cure of Gonorrhea.**—A. L. Wolbarst concludes that no patient can be declared cured of gonorrhea unless the following tests have been carefully and repeatedly performed: (1) Microscopic and cultural examination of the centrifugated morning urine, as well as the washings from the irrigation of the anterior urethra. (2) Miscroscopic and cultural examination of the urethral discharge—whether spontaneous or artificial. (3) Microscopic and cultural examination of the massaged secretion of the prostate and seminal vesicles. (4) Urethroscopic examination of the anterior and posterior urethra. (5) Complement fixation test. (6) Skin reaction and hypodermic injection with gonococcus vaccine (still *sub judice*). Should all of these tests prove negative repeatedly, one may then feel that as far as present knowledge permits, the patient may be declared cured; but the physician cannot assume the full responsibility and guarantee the cure. The patient himself must assume that responsibility.

3. **Early Diagnosis and Operation for Gallstones.**—G. Torrance quotes Moynihan, Mayo-Robson, the Mayos, and others as to the importance of early operation in gallstones before the development of complications. On the continent of Europe surgeons have been slow to advocate early operation. Mayo in 4,000 cases gives an average mortality of 2.75 per cent. In the simple, uncomplicated gallstone cases the mortality was less than one-half per cent. The author reports a series of thirty-five cases illustrating his thesis.

4. **Physical Examination of Health Department Employees.**—C. B. Slade analyzes the results obtained in 696 examinations. Seventeen per cent. of the individuals examined had defective digestion, and habitual constipation was usually an associated condition. Defective eyesight was found in 19.3 per cent. of the cases, and defects of the nose and throat, needing attention, were found in 8.9 per cent. Cardiac derangement was found in 13.2 per cent. of the individuals examined. Some form of lung disease, active, quiescent, or healed, was found in 4.4 per cent. Albuminuria to a slight amount was detected in so large a number—30 per cent.—that the author is inclined to believe that the chemical tests were too fine. One-third of the individuals were in obvious need of medical advice and 24.6 per cent. were in actual need of treatment.

5. **Hemorrhoids and Hyperchlorhydria.**—E. Palier has found that hemorrhoids are invariably accompanied by hyperchlorhydria, permanent or transient. He suggests the following method of treatment for an attack of inflamed hemorrhoids. Give the patient a teaspoonful of sodium bicarbonate. This alone will in many instances relieve the congestion and pain in half an hour, and if the patient is constipated, will cause a semisolid evacuation of the bowels with very little pain. In patients suffering from chronic constipation, magnesia usta can be given afterward. It is best to give the patient in addition to the soda a hot sitz bath for about half an hour. Put the patient in bed for the day and let him apply lead and opium lotion to the anus for a few hours. On the following morning the patient will be able to get up and attend to his business. He will be well or practically well as long as his stomach remains in good condition. In those suffering from transient hyperchlorhydria the piles will get worse with the aggravation of the gastric condition. When hemorrhoids supervene during an attack of diarrhea, the latter must be checked, and the former will thereby be relieved. Hamamelis, internally and locally, does good. What has been said above applies to acute or subacute attacks or exacerbations of chronic hemorrhoids. As for the affection, while it is in a quiescent indolorous state, the best thing is operative interference of some sort; but patients, as a rule, even intelligent ones, do not pay attention to this ailment while it does not bother them. By paying attention to their stomach, patients can remain free from pain and bleeding of their hemorrhoids for many years.

1. Institutional Mortality of the Newborn.—L. Emmett Holt and E. C. Babbitt analyze a series of ten thousand consecutive births at the Sloane Hospital for Women, New York. The deaths in the hospital during the first fourteen days were 3 per cent. of the living births. For half this number prematurity was responsible. Forty-eight per cent. of the total deaths and 66 per cent. of those due to prematurity occurred on the first day. Congenital weakness and atelectasis together made up 58 per cent. of the total deaths. The mortality from conditions intimately connected with delivery—accidents of labor, hemorrhage, sepsis and asphyxia—together made up but 20 per cent. of the deaths of the first fourteen days. Malformations and congenital diseases other than syphilis caused 4 per cent., and syphilis 4 per cent. The only important disease developing after birth was pneumonia. Stillbirths must be reckoned as one of the large problems in infant mortality; they are one and a half times as many as the deaths from all causes during the first two weeks. Except for the larger rôle played by syphilis, the causes of stillbirth in no way differ from those which produce death during the first days of life. When one comes to consider to what degree preventive measures might influence the mortality of the first two weeks of life, two things stand out prominently: The great number of deaths from congenital weakness can be reduced only by care of the mother during her pregnancy; the number of stillbirths and the deaths from causes connected with parturition can be largely reduced by good obstetrics.

2. Effect of Colon Bacillus on Kidney.—I. S. Koll concludes from his experiment that a non-traumatized kidney in the absence of ureteral obstruction overcomes spontaneously the invasion of virulent microorganisms. It appears that the blood-stream is the means of extension of these infections from the pelvis to the cortex, from the cortex to the pelvis, and in all probability from the periureteral tissue to the renal parenchyma. This is based on the fact that the glomeruli are the structures mostly involved. The pathological changes are due to a direct toxic action and the soluble toxins of the organisms are carried to the opposite kidney, where a similar picture is seen.

5. Pituitary Extract in Nasal and Throat Surgery.—H. Kahn and L. E. Gordon find that the coagulation time of the blood is materially reduced by the hypodermic administration of pituitary extract. The hemorrhage following nasal and throat operations, especially operations on the turbinals, is much reduced by this administration. The effect on the blood-pressure of children is variable, as follows: Systolic pressure is increased in 55.31 per cent. of the cases, reduced in 36 per cent. and unchanged in 8.5 per cent. Diastolic pressure is increased in 35.5 per cent. of the cases, reduced in 35.5 per cent. and there is no change in 29 per cent. Pulse-pressure is increased in 61 per cent. and decreased in 39 per cent. of the cases.

7. Congenital Scoliosis.—H. B. Thomas reports a case of this condition, and in discussing the etiology discards those cases which are the direct result of bony congenital defects. The following theories are left for consideration: heredity and intrauterine pressure, injury, paralysis, rickets, and anomalies of muscles. From the examination of a number of cadavers the author finds that in a majority of instances, owing to the inequality of length of two opposing muscles, there is an uneven muscle attachment. Such anomaly he regards as a cause for beginning asymmetry, congenital or acquired, whose exaggeration by position would produce scoliosis.

9. Ankylosis of Elbow.—W. R. McAusland presents a review of the methods that have been employed to cure this condition. Murphy was the first to recommend the use of fat and fascia interposed between joint surfaces, but the author from his experience thus far believes that there are certain objections to the use of fatty tissue, such as embolus, fatty necrosis from poor circulation and, as happened in two of his own cases, skin necrosis, due to the use of the flap of the tissue holding its blood supply. He nevertheless reports these cases together with two others in which, after trimming the joint after breaking up the ankylosis to as near an approach to the normal joint as possible, removing only such bone as would prevent free motion, he interposed fascia transplanted from the thigh with a more satisfactory result.

1. Estimation of Physique and Stamina for School Purposes.—A. A. Mumford, in discussing standards of bodily growth as standards of physique notes that a formula was suggested in 1900 by Pignet, which formula consists in saying that if from the numeral indicating the height in centimeters there are subtracted the two numerals representing chest girth in centimeters and the weight in kilograms, a numeral is obtained which in the absence of organic disease bears constant relation to general bodily vigor. Standards of nutrition are generally of more value for school purposes than standards of growth, at least for the early ages of life, for growth is only one of the results of nutrition. Among the estimates based on medical inspections are those concerned with the rate and degree of bodily development, the development of the respiratory apparatus, and the condition of the musculature of the neck and spine. There are practically three

natural physiological types of development of the neuromuscular system: (1) The adaptation for the exhibition of massive weight; (2) the adaptation for bodily vigor and bodily strength; (3) the feeble development of the larger limb muscles and bony framework, and the considerable development but irregular distribution of nervous energy.

2. **Frostbite.**—A. W. Mayo-Robson discusses this subject, particularly with reference to the prevalence of frostbite among soldiers. The best treatment at first is friction with snow or cold water in a cold room, the changes to a warmer atmosphere being gradually brought about. Frictions with turpentine and oil or with alcohol and soap liniment are useful remedies in the early stage, and after the friction the limbs should be raised on pillows and swathed in cotton-wool, which can be held in position by bandages applied loosely so as to avoid any danger of constriction. If blisters form, or discoloration of the toes or other parts shows that gangrene is probable, the whole foot should be sterilized by rubbing with oil of turpentine to cleanse the skin or with alcohol containing 1 in 500 biniodide of mercury, after which strips of sterilized double cyanide gauze should be applied between the toes and the same gauze made to cover the whole foot; which is then enveloped in sterilized cotton-wool. Any blisters —which will be found to contain dark blood-stained fluid—should be snipped and carefully dried and dressed with the alcohol and biniodide lotion. Painting the foot with tincture of iodine would probably be quite as effectual, as an antiseptic, as the alcohol and biniodide solution. Every effort should be made to keep the parts dry and sterile, and if gangrene occurs the surgeon should on no account make too great haste to amputate, as the tissues adjoining the line of demarcation become more and more healthy and the line of granulation tissue between the dead and living tissues, if kept aseptic, gives rise to little discharge and can be kept aseptic by a daily dressing with the alcohol solution. Frostbite is a preventable condition. In soldiers tight boots and tightly applied puttees are important factors in its causation.

3. **Clinical Value of the Abderhalden Reaction.**—J. O. Gavronsky notes that the cardinal question as to the practical value of this reaction is still unsettled. There is a considerable divergence of opinion as to the possibility of demonstrating the presence of specific ferments in the blood serum, and of making use of such demonstration for diagnostic and other practical purposes. Were this possibility once established one would attain the solution of many problems of primary and vital importance. It is not, of course, a diagnosis of pregnancy in the first week that is going to bring about a serious alleviation in human suffering; moreover, gynecologists will readily agree that it is very rarely that they are in doubt as to the differentiation between an ectopic pregnancy and a salpingitis, or between a pregnancy of the first few months and a myoma. Of real importance would be the fact that one could make an early diagnosis of malignant tumors, or give a prognosis, after operation in a case of malignant disease, or differentiate between hysteria and epilepsy in doubtful cases. As the result of his investigations the author draws the following conclusions: The serum of pregnant patients contains proteolytic and peptolytic ferments which are able to decompose any kind of coagulated albumin or peptone prepared therefrom. Whenever proteolytic ferments are found in the serum of patients with malignant tumors or other diseases, they have the property of acting in the same non-specific manner. The serum of perfectly normal individuals does not contain these ferments, at least in the great majority of cases. A negative result, when one attempts to demonstrate proteolytic ferments in suspected cases of pregnancy or carcinoma, speaks strongly against the existence of these states, and therefore may be of value in practice.

7. **Effect of Calcium Chloride on Hemolysis.**—W. W. C. Topley and S. G. Platts state that their experiments afford no evidence of any protective influence exerted by calcium chloride on the red cells of animals subjected to the action of a specific hemolytic serum, though this salt serves to inhibit the lysis of the same cells by the same serum in test-tube experiments. Conclusions as to the therapeutic value of this and similar salts based on experiments *in vitro* must therefore be held to be invalid.

6. **Bilateral Optic Neuritis Due to Sphenoidal Sinusitis.**—A. A. Bradburne reports a case of this condition in a woman aged 27 years. The case presented several features of interest. When first seen the only objective signs were the slight weakness of the left abductor and the suspicious neuritis of the left disc. The length of time which elapsed before the neuritis became definitely evident on the face of the disc pointed to a lesion affecting the nerve a long way behind the eyeball. This was further confirmed by the absence of pain or tenderness on pressure over the eyeball and the primary implication of the sixth nerve. The implication of this nerve still further assisted the localization of the seat of the mischief, for such could scarcely be anywhere else than at its situation on the body of the sphenoid where it traverses the cavernous sinus alongside the carotid artery. By direct extension of the mischief forwards the implication of the optic nerve can be explained, for, as pointed out by Onodi in his investigations on the relations of the optic sulcus, this canal can be formed entirely by the bone forming the sphenoidal sinus. It is possible that in this case the sixth nerve may have had an abnormal relationship to the carotid artery in the cavernous sinus, and instead of lying external to the artery might have lain on its mesial aspect in contact with the bone. This theory would explain why the occurrence of abducens paresis has not been recorded before. Again, the localizing feature of this paresis enables one to put out of court any liability on the part of the posterior ethmoidal cells, which, as is well known, are a frequent cause of optic neuritis. A more difficult symptom to account for is the complaint of occipital pain, which is almost pathognomonic of sphenoidal sinus trouble. In the author's opinion such may be attributable to implication of the sympathetic plexus around the carotid artery.

7. **Effect of Daylight and Drying Tubercle Bacilli.**—L. Findlay and W. B. M. Martin find that the bovine type is distinctly more susceptible to the prejudicial effect of ordinary atmospheric influences (daylight and drying) than is the human type of tubercle bacillus. This difference may in part explain why aerial infection with the bovine type is so infrequent in human beings.

Berliner klinische Wochenschrift.

December 21, 1914.

Parenchymatotoxic Action of the Syphilis Contagium in Early Visceral Syphilis and Taboparesis.—Bushke and Michael refer to precocious jaundice as one of the earliest and most frequent symptoms of visceral syphilis. In about 10 per cent. of cases this symptom leads to acute yellow atrophy, which suggests that the primary affection of the liver is acute parenchymatous hepatitis; but thus far no one has found spirochetes in these livers. Hence inflammation and atrophy in this organ must be regarded as of toxic origin. A corresponding toxic nephritis, or nephrosis, is known to occur, and both organs are similarly attacked in the toxemia of pregnancy and in phosphorus poisoning. The early syphilitic hepatitis and nephritis are sometimes amazingly influenced by a few injections of sublimate, which exert no action upon the spirochetes in the skin lesions. The results are therefore to be interpreted as antitoxic and not as spirillocidic. It is quite possible that early syphilitic diabetes is due to a specific parenchymatous pancreatitis. However, the most striking example of toxic syphilitic affections is taboparesis. The toxic nature of the latter appears also after a comparison between tabes and certain effects of ergot and lead. But unlike the case of the abdominal viscera, spirochetes have been found alive in the nervous centers, while certain histological finds, as well as the frequency of lymphocytosis in the spinal fluid, suggest infection rather than purely toxic phenomena. On the other hand the parenchymatous changes in the nervous centers in taboparesis apparently indicate the presence of a mixed toxi-infectious condition, which appertains rather to the late stages of syphilis. The precocious form of syphilis of the brain, or early cerebral syphilis, is of course an infectious manifestation. At present then taboparesis is possibly a unique manifestation of syphilis. Spirochetes enter the nervous center, causing no reaction of any sort, although perhaps supplying toxic matter for the blood. Then after years of latency they become activated, virulent, and infectious.

Dostoyevsky as Psychopathologist. — Münzer begins a serial article on this subject. Like Poe the subject of this study antedated by far the psychiatrist in the recognition of degeneracy, phobias, obsessive states, and other expressions of psychopathy which stop short of true phychoses. The father of the Karamasov brothers was a profligate who obtained his wife (and her money) by seduction. He was always wholly indifferent to his home and family. His second wife he ignored, filling the house with loose women. He lived only for carousing, and finally became a parasite. Once when drunk he attacked an idiot girl, apparently for the mere experience of intercourse "with a beast in the form of a woman." Many other deeds show the man as morally insane, "without ethical conceptions and normal inhibitions." Alcohol and sensuality produced a vicious circle. The eldest son is summed up by the author as unstable, fickle, and of weak will. He never acquired self-mastery. Unlike his father, he was naturally of good disposition, and under proper environment would have made a useful citizen. The weakness of will, however, under certain provocation, could transform such a man into a violent personality, and this one finally murdered his father. This type of degenerate shows the greatest contrasts. The second brother began life with a fine mind, was noted however for cynicism, a trait inherited from his father. He did not meddle in his older brother's affairs, even when he knew he was planning the murder of their father. Whether because of remorse or from some other cause he became frankly insane. Many other accounts of psychopaths follow.

Deutsche medizinische Wochenschrift.

December 31, 1914.

Proposition for a Joint Research on Tetanus.—Stricker suggests the following schematic arrangement for filling out blanks. The name, regiment and rank should first be noted. This may be of value in the case of sequelæ—contractures, neuralgia, etc.—which may be present many years after the experience. The time and place of the skirmish or battle should be recorded, because there is sometimes in evidence a special virulence in cases which develop in a particular locality. The site and nature of the wound are of the greatest importance, for the nature of the offending projectile is included here. The time and locality at which the disease first appears possess much significance. In the Franco-Prussian war two-thirds of the cases in one series developed between the fourth and eleventh day. Finally the treatment should be given in full, beginning with the prophylaxis, which is practically the same in all cases. The younger generation of practitioners may not be able to recognize the numerous insidious prodromes of the disease, and after these have appeared prophylaxis is out of the question and treatment must be pushed. Some prodromes are change of disposition to an anxious, lacrymose behavior; insomnia, impatience, prickling sensations in the face, failing appetitie, increasing thirst, pain in the wound, even if the latter is healing well. The treatment must be recorded under the different resources in common use.

Shot Wounds of the Large Blood Vessels.—Kappis expresses himself as follows at the close of an article on this subject: The modern pointed bullet is not by any means the sole cause of vascular wounds, but is much the more frequent cause, especially when traumatic aneurysms form. Hence in warfare to-day injuries of these vessels occur more frequently than in former years. In regard to treatment even the most experienced surgeon should not ligate large vessels save in the most urgent cases. Unless gangrene is impending compression is the proper treatment in many cases. Bandages may be left *in situ* for several weeks, or until the patient has had time to be interned in a central hospital.

Skull Surgery on the Field.—Erhardt concludes a serial article based on 23 cases as follows: Four patients died of tetanus and five of meningitis, while two received some benefit and twelve have recovered, or will recover. Can the above lethal complications be prevented? The supervention of both can be readily explained, for the soldiers lie on the ground, their heads and faces covered with earth. The projectile inevitably forces the latter into the wound, and the encephalic tissues can hardly be cleansed like surface wounds, nor does self-cleansing through hemorrhage occur. Tetanus thus acquired is peculiarly resistant to serotherapy. In several of the author's cases the brain prolapsed.

Narcosis Asphyxia after Laparotomy. — Kirstein seeks to explain these cases as follows: This condition doubtless appears in the third stage of narcosis, after cessation of the powerful "irritation," much more frequently than is commonly believed, and might be recognized if due heed were paid to the antecedent circumstances. Could the latter be recognized in time these fatal cases might be prevented. Fortunately these deaths are very rare. The mischief is already in progress when the first manifestations of narcosis appear, because the cells of the predisposed patient have a limited tolerance to narcosis owing to their small oxidative capacity. The course of the asphyxia is so rapid that the condition is usually realized only when it is too late to interfere.

Insurance Medicine.

The Symptoms and Physical Signs of Approaching Organic Disease.—Dr. Louis Mix outlines a systematic method of studying this subject, beginning with the skin. Observation of the skin of the body is often rewarded by the detection of underlying organic defects, which at first sight, might be easily overlooked. The general nutrition, amount of subcutaneous fat present, color, and perspiration, and faint traces of edema are all to be studied. A defective abdominal panniculus adiposus is always suspicious. An excess of perspiration especially in persons over forty, may indicate dyspnea, whether pulmonary or cardiac, and is found in all conditions of engorgements of the systemic circulation. A dry skin indicates disease in which the kidneys are carrying off an excess of water, as in chronic interstitial nephritis, often without the presence of casts or albumen, and glycosuria and diabetes with polyuria. Pallor may indicate grades of cyanosis. A pale skin will offer suspicion of blood states which might not otherwise be suspected. In general the color of the skin is due either to the fullness of the vessels, the amount of hemoglobin contained in the blood, or to the thickness or thinness of the skin. Fright may cause pallor. A lasting pallor is characteristic of the early stages of leukemia pseudoleukemia, and secondary anemias, especially when coming on slowly and lasting over a period of time. Secondary anemias of vast importance are caused by intermittent bleeding piles—sometimes without the knowledge of the patient—carcinoma and nephritis; also obscure diseases of the alimentary tract, female genitalia, and specific infections. A mild degree of cyanosis showing only in the cheeks, lips, finger nails, and tips of ears may occasionally occur in an involvement of the heart, or of oxygenating power of the lungs; to the narrowing of the large air passages through disease or tumors; cardiac disease, especially of the right side. In these cases, oftentimes, the insufficient accentuation of the pulmonic second sound assumes great diagnostic value. The slightly yellow and the bronze skin are only too well known. Edemas are important because they are so frequently overlooked. Turning now to the regional examination of the patient, the forehead should be examined for scars, no matter how small, and an adequate explanation should be demanded of the patient. The face occasionally indicates the oncoming of acromgaly, myxedema, paralysis agitans, or exophthalmic goiter. Observation of the relative width of the space between the upper and lower lids when the eyes are opened will sometimes lead to a thorough examination of the thyroid and of the body for signs of thyroid intoxication. Chronic alcoholism frequently betrays itself in the face. The face, while not exactly edematous, does contain too much fluid. The eyes and pupils indicate much to a keen observer. Very slight traces of edema of the upper lids may foreshadow nephritis or trichinosis. Of course, the Argyll-Robertson pupil is now never overlooked, but it may be present in only one eye. Sometimes the pupils react to light with extreme sluggishness, and with a tendency for the pupil to return after the preliminary contraction from the light to its former size. The size of the pupils is of great importance. The wide pupil, abnormally so, may be indicative not only of hysteria and neuroses of various types, but also of chest and cerebral diseases. Myosis is of more importance than mydriasis. The narrow pupil occurring in old age needs no attention, but that which is due to tabes and paretic dementia cannot be too strongly insisted upon. Small pupils may indicate drug addictions as morphine and its various alkaloids, or cocaine. Occasionally one pupil is myotic, the other normal. This may happen in an aneurysm of the ascending portion of the aorta, or in any condition which allows the compression of one or the other of the sympathetic cords. Inequality of the pupils alone may indicate aneurysm, syphilis, or an irritated cervical sympathetic nervous system, but inequality plus irregularity can be looked upon as a sure sign of an antecedent syphilis. Observations of the ocular motions gives much information. Ptosis, which in about 70 per cent. of cases marks the the existence of cerebral syphilis, is sometimes reduced to an exceptionally small amount and can be overlooked in an ordinary examination. The nose indications are not of as much importance as they usually accompany other recognizable pathological conditions. The lips, especially when sores are present, need intelligent examination. The examination of the tongue may give valuable indications. Tremor is found in the alcoholic and in those afflicted with nervous system conditions. A clean tongue, combined with other symptoms, may indicate duodenal ulcer and hyperchlorhydria. The mouth should be examined for mucous patches, or ulcers indicative of alimentary trouble. The neck shows the condition of the glands found in that region. Tuberculosis, syphilis, and thyroid conditions are to be detected here. Observation of the finger tips may disclose the existence of an unsuspected bronchiectatic cavity, which is exceedingly hard to demonstrate. These cavities are manifested sometimes by enlarged drumstick fingers and a downward curve of the nails. Usually such fingers are associated with marked degrees of cyanosis. The movements of the hands may disclose much toward diagnosis. A mild degree of tremor may be only nervousness, or combined with other symptoms, may indicate alcoholism; the tremor in exophthalmic goiter, and the intention tremor in cases of multiple sclerosis. The back should be examined for spinal curvatures, or sacroiliac disease; tumors due to an aneurysm or a perinephritic abscess. The examination of the chest is so well taught and understood that little need be mentioned here, beyond the significance of Litten's sign. It is the fitting shadow occurring on the edge of inspiration over the ninth and tenth intercostal spaces, particularly on the left side, and is proof positive of the soundness of the lower portion of the pleural cavity. Its absence in persons not too fat should always necessitate a careful examination. In the examination of the cardiovascular apparatus attention must be centered upon the arteries and pulse. The heart, of course, should always be examined. The important arteries to be observed are the brachial, radial, and dorsalis pedis. The pulsations of the brachial artery ought not to be visible in a healthy person. They may be visible, however, without the artery being lengthened, but, if an arteriosclerosis be present, the artery is not only visible with each pulsation. but spreads out and therefore moves. A normal radial is felt only when the pulse wave is passing through it, the sclerotic radial is felt all of the time.—American Life Convention.

Book Reviews.

Die Entstehung und Behandlung der Karzinome. Von Hofrat Dr. A. Theilhaber in München. Paper, 182 pages, with 17 illustrations. Price 7 marks. Berlin: S. Karger, 1914.

By way of introduction Theilhaber says: "Very frequently one hears that the genesis of cancer, as of the other new growths, is shrouded in obscurity. One knows practically nothing of its origin. Such assertions are too pessimistic. To-day we really know more as to the cause of the development of cancer than of the majority of other diseases." From this one would be led to imagine that the author has at last solved the problem upon which so many investigators have labored in vain, or has at least evolved a plausible new theory, but such is not the case. After reading the 55 pages devoted to a discussion of "A. The Local Causes" and 37 more pages of "B. The Humoral Causes," we have found nothing convincing and get back to just where we started—the underlying cause of cancer still remains "shrouded in obscurity."

Theilhaber then discusses the prevention of cancer; the fate of the remaining carcinoma cells left after operation or *x*-ray treatment; the development of recurrences; the therapy of carcinoma, and the prevention of recurrences. A six page bibliography, almost exclusively German, is appended.

In the section on treatment the usual conclusions are reached as to the desirability of operation with total eradication of the growth, but if the number of cancer cells left is not large he believes there may be spontaneous resorption. Most of this section is devoted to the consideration of other methods of treatment, namely, the *x*-ray and radioactive substances, diathermy, fulguration, chemotherapy, ferment therapy, serum therapy, toxin therapy, injection of tumor extracts, autoserotherapy, and the injection of organ extracts. The *x*-ray and radium have been of service, especially in the superficial growths, but in the deeper growths may do more harm than good and actually stimulate the cancer cells. He does not agree with Wickham in the statement that malignant tissues display a special and very selective susceptibility to the influence of radium, but thinks the cancer cells are merely more sensitive and the normal tissues do not escape unharmed. The de Keating-Hart method of fulguration is not considered to be of much value. While the book contains very little that is really new, it is well worth reading, since it gives opinions formed after a careful investigation of the whole subject and probably reflects the consensus of German opinion, where so much faith has been shown in the efficacy of the *x*-ray and radioactive substances.

Venenpuls und Herzschallenregistrierung als Grundlage für die Beurteilung der Mechanischen Arbeitsleistung des Herzens. Nach eigenen Methoden. Von Dr. med. Reinhard Ohm, Stabsarzt an der Kaiser Wilhelms Akademie für das militärartzl. Bildungswesen. Price 1 Mk. Berlin: August Hirschwald Verlag, 1914.

The author's method of diagnosis of mechanical capacity of the heart rests on the principle of direct transmission. Prof. Dr. Friedrich Kraus in his preface remarks that Ohm's inclusion of an electrocardiograph in his apparatus is especially adapted to help to analyze certain difficult problems of cardiac arrhythmias, for instance, the arhythmia totalis.

Diseases of the Skin Including the Acute Eruptive Fevers. By Frank Crozer Knowles, M.D. Instructor in Dermatology, University of Pennsylvania; Dermatologist to the Presbyterian, the Howard, the Children's and the Babies' hospitals; Assistant Dermatologist to the Philadelphia General Hospital, the Dispensary of the Pennsylvania Hospital; Consulting Dermatologist to the Church Home for Children, the Baptist Orphanage, the Southern Home for Destitute Children, the Eastern State Penitentiary and the Burd School; Member of the American Dermatological Association; Fellow of the College of Physicians, etc. Octavo of 546 pages with 199 illustrations and 14 plates. Price $4.00. Philadelphia and New York: Lea & Febiger, 1914.

This volume has been prepared as a guide for the student and the general practitioner in the study of dermatology and the writer has endeavored to cover all the eruptions that occur on the skin and contiguous mucous membranes. In order to make the work more complete, not only the exanthemata are included, but also the acute eruptive fevers that are constantly or occasionally accompanied by a dermal outbreak. He suggests that the practitioner who is refreshing his memory on cutaneous eruptions, and the student who is just entering upon the study of dermatology, should first obtain a working knowledge of the common skin diseases, rather than those which are described as rare. The numerous practical illustrations will prove of help both in the diagnosis and the differentiation of the various dermatological conditions. Therapeutic recommendations have been confined to remedies he has successfully used; he has not introduced a large number of prescriptions which might be confusing. The exact method of using applications has been particularly emphasized under the common diseases. The special methods of treatment, such as the *x*-ray, Finsen light, radium, carbon dioxide snow, therapeutic lamps, and vaccine, including tuberculin, have been fully outlined. Syphilis because of its importance has been treated in considerable detail, including the methods of straining and experimental studies with the *Spirocheta pallida*. The exact technique for giving salvarsan and neosalvarsan, and the after-effects, are described, and the Wassermann, lutein, and various tuberculin tests are given in detail. This book should serve a very useful purpose, particularly as a diagnostic guide, to the student and general practitioner.

Auricular Flutter. By William Thomas Ritchie, M.D., F.R.C.P.E., F.R.S.E., Physician to the Deaconess Hospital; Assistant Physician to the Royal Infirmary; Lecturer on the Practice of Medicine, School of Medicine of the Royal College; Lecturer on Clinical Medicine in the University of Edinburgh. Price $3.50. New York: Paul B. Hoeber, 1914.

It is only recently, scarcely more than a decade, that clinicians have paid any attention to the auricles of the heart; formerly diseases of the valves only were looked upon with any degree of apprehension, or at least they alone were regarded as susceptible of accurate diagnosis, though hypertrophy and degeneration of the ventricles were also held responsible for many of the consequences of "heart disease." Now, however, it is the auricles that are charged with many cases of heart failure, and the study of their condition and their pulsations, rendered possible by the modern method of clinical investigation introduced by Mackenzie, is receiving more and more attention. We are constantly hearing new things about the muscles, and among the newest of these is auricular flutter, a term first employed by Jolly and the author of this book three years ago, though the condition itself was described somewhat earlier. In this work Ritchie considers the disorder in all its aspects, his account being based upon a study of eleven cases occurring in his own practice and forty-two recorded in the literature. The practitioner wishing to acquaint himself with the disease in its etiological, diagnostic, and pathological relations will find nowhere a better or more authoritative account than that of Ritchie.

Essentials of Physiology. By F. A. Bainbridge, M.A., M.C. (Cantab), D.Sc. (London), F.R.C.P.; Professor of Physiology, University of Durham; and J. Acworth Menzies, M.D. (Edinburgh); Lecturer on Physiology, University of Durham College of Medicine. With 134 Illustrations. Price $3.00. New York: Longmans, Green & Co., 1914.

In this volume the authors have brought together, in a concise and readable form, the fundamental facts and principles of physiology. Many a physician would gladly keep up with the modern advances in physiology, but he is repelled by the details of laboratory and experimental work with which most of the standard works are loaded. For such readers, as well as for students preparing for examinations, the present work is well adapted.

The Germ-Cell Cycle in Animals. By Robert W. Hegner, Ph.D., Assistant Professor of Zoology in the University of Michigan; Author of "An Introduction to Zoology" and "College Zoology." Price $1.75. New York: The Macmillan Company, 1914.

This volume contains an outline of cellular biology as it is understood at the present day. The subject-matter of this book is necessary not only for the student of general biology, but also for the medical reader who is interested in the problems of cell activity, and such subjects as oogenesis and spermatogenesis. The book is well illustrated and the bibliography is of unusual excellence.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, Held January 7, 1915.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

Report of Board of Trustees and Treasurer.—This report stated that during the past year the Academy property had been put in good physical condition and was fully protected by workmen's compensation, accident and fire insurance. Since the last report the Academy had been informed of bequests in its favor made by Dr. Everett Herrick, who left $25,000 to the General Permanent Fund and $25,000 to the Library Fund, and by Dr. Joseph D. Bryant, who left one-seventh of his residuary estate to the Academy to be paid in case of the death or remarriage of his widow. The Endowment Fund had been increased by $1,500. The General Permanent Fund was increased $150. The Library Committee had made arrangements with the First District Dental Society for an annual donation of $75 for the purchase of books, etc., on dentistry. The Treasurer's report which was submitted with that of the Trustees showed that the trust funds of the Academy now totaled $687,090.

Report of the Public Health, Hospital, and Budget Committee.—This report had already been submitted to the fellows of the Academy and showed the wide and varied activities of this committee. Among the subjects with which they had concerned themselves during the past year were the following: Standards for tonsil and adenoid operations, gonorrheal vaginitis, mortality from degenerative diseases, street cleaning, cooperation with the Police Department, standards for physical examination for candidates for various city offices, standard for physical examination of children between the ages of fourteen and sixteen years working in factories, mental fatigue in school children, open-air classes in schools, the periodic examination of school teachers, pure food and proper nutrition, the coroners, autopsies, restriction of the free sale of bichloride of mercury, study of the municipal budget for 1915, public health legislation, advertisement of harmful drugs or quack treatment, public health instruction in medical schools, revision of the City Sanitary Code, subway sanitation, physical and mental examination of immigrants, and the New York State census of 1915.

Resolution.—The following resolution presented to the Academy by the Council was adopted: That the President be authorized to appoint each year a committee to be known as the Public Health Committee, and to fill such vacancies as may occur in it, or make such addition as may seem best. This committee shall be authorized to cooperate with public health activities and to make studies of, and issue statements upon matters pertaining to, public health and hospitals; but such statements shall not be issued until approved by three-fourths of the Committee and by the President of the Academy of Medicine. Subject to these provisions the Committee is authorized to appear before any committee, board, legislative, or other body, in order to make statements and express opinions on matters relating to public health and hospitals.

Address of Retiring President.—Dr. WILLIAM M POLK, in a brief address, referred to his period of office as having bestowed upon him some of the pleasantest moments of his life, but thought that possibly many of the fellows of the Academy failed to realize the responsibilities that were assumed by the officers of such an organization. In closing he stated that his reluctance in laying down his task was tempered by the fact that it was to be assumed by Dr. James whose worth and ability to meet the responsibilities of the office were so well known that it was not worth while to take time to recall them.

Address of Incoming President.—Dr. WALTER B. JAMES said that after listening to Dr. Polk and looking about the room at the lineaments of those who had preceded him he wondered that he should attempt a work that they had so well fulfilled. He recalled the circumstances under which the Academy was founded and said that the fact that the first meetings were held in the Museum of Natural History augured well for the future of the Academy, since it gave a background that took in other interests than that purely medical and furnished a broader viewpoint than the merely professional one. Dr. Chisholm, in discussing the subject of specialism, had said that specialism involved self sacrifice. The specialist was undoubtedly of greater value to the public than the general practitioner but it was very questionable whether specialism was of advantage to the physician himself because it narrowed his point of view. On this account it was well that in the early days of the Academy they should have been associated with collateral branches of knowledge and thus have had the tendency to narrowness counteracted. For this same reason they should still today give themselves occasionally to the contemplation of matters not strictly medical and surgical. It did them good to turn back and see what the medical worthies of the past had done. It was fitting that they should ask scientific men from other places to come to them and to talk of an anatomist who lived many years ago and whose services to medicine and to the world at large had been of incalculable value. It was highly appropriate that they should devote an evening to Vesalius, and it was equally appropriate that their distinguished confrère, Dr. Welch, who was so well known to New York that he needed no introduction, should give of his store of knowledge on this subject.

Vesalius and the Spirit of His Time.—Dr. WILLIAM H. WELCH of Baltimore made this address, which he prefaced by saying that he had only been asked to be present and to make a few remarks on "Vesalius and the Spirit of His Time," and was not aware until he saw the program that he was to make an address; he was, therefore, in somewhat of an embarrassing position. However, he understood that the occasion was informal and that he might use topics more or less remotely related to the subject. There were many points of view that one might take in celebrating the quadricentennial of the birth of Vesalius. This was the period of the renaissance, the revival of learning, the reformation, and this setting of the life of Vesalius would in itself be a large theme, but this part of the subject had been so well done by Dr. James J. Walsh in the "Century of Columbus" that he would not undertake it. Perhaps Dr. Walsh had been too enthusiastic, but nevertheless he had presented an imposing array of knowledge. Vesalius lived in a time when great events were transpiring that enlarged the boundaries of human knowledge and this was particularly true of medicine. At this time the physician was also the botanist and, the zoologist; he was a student in all the sciences based on observation. And of all the anatomists Vesalius did most to place anatomy on the solid basis of observation. It would also be appropriate to view the subject of the evening from the biographical standpoint, but the biography of Vesalius was so accessible that they need not linger here. Again one might consider his Teutonic origin and its influences, or his life in the university. On this occasion it was of melancholy significance that the University of Louvain, in which he received his early training, had been planning to celebrate the quadricentennial of Vesalius this winter when it suffered ruin and its professors were scattered. Vesalius began the study of anatomy at the age of fifteen and remained three years at Louvain. He then went to the University of Paris and studied for three years. Here he studied with Jacobus Sylvius. The one blemish on the character of Vesalius seemed to be his ingratitude toward Sylvius. Sylvius and his school were Galenites while Vesalius made observation and not tradition the basis of anatomical knowledge. However, without arguing the differences of these two anatomists which had been so ably discussed by Dr. Frank Baker, one should not overlook the fact that the contributions of Sylvius to anatomy were not to be ignored. Other famous anatomists associated with Sylvius at Paris were Andernacus Guinterius and Carolus Stephanus (Charles Esticune) who published a work in 1545 which was begun long before the figure of Vesalius appeared. Again, one might consider the life of Vesalius in Italy where his colleagues were R. Columbus, Fallopius, and Eustachius, who rivaled him in some respects, and surpassed him in others. They regarded themselves still as Galenites but were really no more Galenites than Vesalius himself. He remained at Padua from 1537 to 1542, when conditions became so intolerable that he relinquished the fight, and in a moment of despair, burned manuscript which there is evidence to believe contained valuable contributions to physiology and pathology. In 1542 he had published the "Fabrica," when he was not yet thirty years of age. During this period he also taught at Pisa and Bologna. In 1546 he became court physician to Charles V and

afterward to Philip II, but his active life as a scientist was over. Certainly life at court could not have been to the taste of an active scientist such as he had been. Then later came the strange pilgrimage to Jerusalem. Many theories were current to account for this. It was said by some to be expiatory; that in performing a post-mortem examination on a member of the royal family he found the heart still beating, and that he was permitted to expiate this offense by a pilgrimage to Jerusalem. That such an occurrence had taken place was highly improbable. It was improbable in view of his knowledge and also because the same accusation had been made against other anatomists. Another theory to account for the pilgrimage was that his domestic relations were unhappy. Whatever might have been the reason, he undertook the trip, and on his homeward pilgrimage was shipwrecked and cast ashore, exhausted and in poverty, on the Island of Zante, where he died in 1564.

The "Fabrica Corporis Humani" was the most sumptuous and glorious work in the history of medicine and copies were much sought after by collectors. The "Epitome" was even more rare than the "Fabrica." It would be very interesting to trace the actual contributions of Vesalius to anatomy. They had been treated in rather a summary way, perhaps because he had so covered the field that he left nothing possible to his time undone. Vesalius was spoken of as the father of anatomy but that was wrong; again he was spoken of as the father of modern anatomy, but Dr. Welch said he preferred to call him the "reformer of anatomy." He had presented the first comprehensive, scientific treatise on anatomy studied for its own sake. Some of his contemporary anatomists still regarded him as a Galenite but he had freed anatomy from the bondage of authority. He started anatomy on the path which it has since followed. Some of his work was of such permanent value that it might still be consulted today. Having furnished the basis of anatomy he had laid the foundation on which physiology, pathology, and therapeutics had been developed. He was the greatest figure in the development of anatomy between Modino and Harvey. Anatomical laboratories existed from the sixteenth century onward and it was perhaps due to the influence of Vesalius and his followers that anatomy had come to occupy a somewhat disproportionate place in the medical curriculum. Dr. Welch spoke further on Vesalius' part in the overthrow of Galenism and also of the influence that Paracelsus exerted in the downfall of the Galenic theory of pathology, and quoted to show how nearly Paracelsus had come to enunciating the germ theory of disease. It was a little disappointing, however, to find how many people in those times died of "polypus of the heart," meaning decolorized blood clots. In closing Dr. Welch again declared that Vesalius had laid the foundation stone of modern medicine as a science.

Anatomical Illustrations before and after Vesalius.—Dr. FIELDING H. GARRISON of Washington, D. C., editor of the *Index Medicus*, made this address which he illustrated by lantern slides. He said that he hoped the lantern slides would afford convincing evidence of the tremendous advance made by Vesalius in the single item of anatomical illustration. The "Fabrica" had never been fully translated and one was apt to ignore the text and base his perception of the greatness of Vesalius upon these pictures alone. Vesalius was to anatomy what Beethoven was to music; he literally exhausted the possibilities of his subject in the time in which his work was done. The work of Vesalius in anatomical illustration might be likened to Beethoven's Thirty-three Variations on a Waltz by Diabelli. Even as Beethoven gave a series of patterns of all the figurations possible on the piano in his time, so the illustrations of the "Fabrica" gave to the post-Vesalian anatomists all the figurations of the human body which were possible to the wood engravers of Vesalius' time. From the extraordinary way in which these engravings were plagiarized and copied by certain post-Vesalian anatomists and book makers it was to be perceived that, with all the technical beauties of Casserius and Bidloo, and with all the exquisite delicacy of Ruysch and Soemmering, hardly any new key, hardly any new note, was sounded until the advent of Scarpa and steel engraving, of Pirogoff and frozen sections, of lithography, photography, and electroplating, microscopical and morphological anatomy, of direct photography from nature and the nude. Vesalius set the vogue in high class anatomical illustration for three centuries until the time of Mascagni, Cheselden, William Hunter, and Soemmerring. Beyond vague references to paradigmata schemata, and diagraphs in Aristotle's "Historica animalium," there was no evidence of anatomical illustration among the ancients, and if these expressions referred to pictures the latter were merely comparative and not human. In the manuscript codices of Moschion, there were a number of stock figures representing the fetus in utero, constantly reproduced, and nude figures in various attitudes were a common feature of miniature paintings in old parchment manuscript. From the twelfth century on there began to appear various manuscript drawings and miniature paintings in the old codices which had been investigated mainly by Sudhoff and Giacosa. The great authority on published anatomical illustrations after the invention of printing with wooden blocks was Ludwig Choulant.

Dr. GARRISON stated that the lantern slides exhibited were from Dr. Frank Baker of Georgetown University who had made a careful and extensive study of anatomical delineation. These slides represented different concepts of the osseous, vascular, and nervous systems, and of the gravida with fetus in utero, showing the remarkable influence of tradition for nearly three centuries. All of the figures had the monotonous attitude of a child's jumping jack which had just been pulled. One of the illustrations was a zodiacal figure or "blood-letting man" from a calendar of 1475. In these the points of election for blood-letting were determined by planetary influences. The figures were quite similar to those in the Hagerstown and Hostetter's almanac of not so very long ago. The exhibit included figures from Phryesen's "Spiegel der Artzny" and écorché or flayed figures from Berngario da Carpi in which the muscles were held up for inspection, a pose which became characteristic of all the later works. There were drawings by Verocchio, Leonardi da Vinci, Michael Angelo, and Raphael. One illustration of a deep dissection of the viscera by Leonardo, Dr. Garrison said, was the most wonderful anatomical drawing of the time and would compare favorably with Max Brödel's rendering of the same subject in Kelly's and Burnam's recent work on "Diseases of the Kidney" (1914). None of these drawings of the great masters were ever published in their time. A picture similar to the latter from the "Fabrica" of Vesalius showed a difference in artistic technique, being more diagramatic and less fascinating than that of Leonardo. While Vesalius might have seen the drawings of Leonardo there was no conscious or unconscious plagiarism, though possibly they might have given Vesalius the happy idea of employing a great artist to illustrate his work, as it is supposed he did. After showing a number of the illustrations of Vesalius, Dr. Garrison showed those of a number of the post-Vesalian illustrators, through all of which the Vesalian influence could be traced.

Portraits of Vesalius.—Professor HARVEY CUSHING of Boston referred briefly to the various fields in which the influence of the renaissance was felt, speaking especially of Italian art and of the influence of Leonardo da Vinci, Michael Angelo and Raphael on the development of anatomical illustration. He showed slides of some of the anatomical drawings of these masters and a number of portraits of Vesalius; some of them were evidently authentic, while the authenticity of others was very questionable. Two were supposed to have been executed by Titian. In closing Dr. Cushing said it was rather strange that in anatomy nothing was named after Vesalius except the small opening in the sphenoid bone and the emissary vein passing through the foramen. He did not know why this was unless because Vesalius had covered the entire ground so well. It was known that he had described the semilunar valves, the trapezius, and the mitral valve for the first time. Some of the lines from Kipling's "Explorer" seemed especially appropriate to Vesalius.

Have I named one single river? Have I claimed one single acre?
Have I kept one single nugget—(barring samples)?
No, not I:
Because my price was paid me ten times over by my Maker.
But you wouldn't understand it. You go up and occupy.

Yes, your "Never-never country;" yes, your "Edge of cultivation"
And "no sense in going further"—till I crossed the range to see.

God forgive me. No, I didn't. It's God's present to our nation.
Anybody might have found it, but—His whisper came to me.

Vesaliana. — In connection with this meeting there was an exhibit of examples of the original editions of the books published by Vesalius. There were also examples of the works of the anatomists who preceded him, including his teachers and contemporaries and also examples of the works of his followers and imitators, and posthumous editions of his plates up to their latest impressions by Leveling in 1742. There was also an interesting group of books from his critics and opponents. The exhibits were from the Library of the New York Academy of Medicine, the Library of the Medical Society of the County of Kings, and by Drs. Harvey Cushing and Edward Clark Streeter of Boston, Dr. Fielding M. Garrison of Washington, Dr. W. B. Coley of New York and Dr. Lewis S. Pilcher of Brooklyn.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Meeting of November 23, Held December 28.

THE PRESIDENT, DR. T. PASSMORE BERENS, IN THE CHAIR.

Reading of Resolutions upon the Death of Dr. H. Seymour Houghton.—Dr. CHARLES N. DOWD read these resolutions.

Reading of Resolutions upon the Death of Dr. L. Bolton Bangs.—Dr. JAMES PEDERSEN read these resolutions.

Election of Officers.—*President*, Dr. Howard Lilienthal; *First Vice-President*, Dr. Frederic E. Sondern; *Second Vice-President*, Dr. George O. Stewart; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. Daniel S. Dougherty; *Treasurer*, Dr. Charles M. Richardson.

Further Observations on the Treatment of Sciatica by Perineural Infiltration with Physiological Saline Solution.—Dr. WILLIAM M. LESZYNSKY read this paper. (See page 211.)

Treatment of Sciatica by Epidural Injection of Saline Solution.—Dr. ISRAEL STRAUSS read this paper. (See page 213.)

Analysis of Narcotic Drug Addiction.—Dr. ERNEST S. BISHOP read this paper. He said that some years ago his definition of narcotic drug addiction would have been a condition based on some inherent weakness of will power and mental stamina; a condition arising from the habitual use of a narcotic drug which causes a deterioration and degeneration of the physical, mental, and moral being; an abandonment of the individual to the pleasure derived from sensuous indulgence; a habit; a vice; a morbid appetite to pander to which the debauchee would go to any length, and loss of self-respect, with no wish to escape from his degrading thraldom. A few months of bedside observation and effort showed him how far this conception fell short of clinical fact. What he had learned he had learned from the study of narcotic drug addictions as a medicoclinical problem, viewing the patient as a sick man, listening to his history and his statements of narcotic drug action, watching his clinical manifestations, and interpreting them in the light of physical action and reaction. In offering this analysis he said he was simply giving the results of personal experience and effort to interpret physical effect upon the basis of physical cause. His present definition of narcotic drug addiction was as follows: A definite physical disease condition, presenting constant and definite physical symptoms and signs, progressing through clean-cut clinical stages of development, explainable by a mechanism of body protection against the action of narcotic toxins, accompanied by inhibition of function and autotoxmia, often displaying deterioration and psychoses which were not intrinsic to the disease but the result of toxemia, anxiety, fear, and suffering. Dr. Bishop then proceeded to elaborate this definition. Observing a number of addicts over a length of time one could not escape the recognition of a chain of constantly present physical manifestations inevitably following the nonadministration of the drug. These might vary in priority of onset, in sequence, and in relative violence of manifestation in different cases, but they were the inevitable result of nonadministration of, for instance, morphine to a morphine addict. They constituted what were called the "withdrawal signs." Every case of well-developed addiction went through several stages definitely marked by clinical signs and reaction phenomena, as (1) stage of normal reaction to therapeutic and toxic dosage; (2) stage of increased tolerance; (3) stage of beginning addiction; (4) stage of established addiction. Most of their cases were in the stage of developed addiction when they were recognized by or came to them for treatment. Developed addiction for a narcotic drug meant physical bodily need for that drug; functional incompetency and suffering without that drug; comparative normality and efficiency only to be secured by the continued use of that drug. Experience had shown that the length of time over which a sufferer was free from his withdrawal agonies was in proportion to the size of his last dose. Each addict showed a definite and measurable daily minimum need for the narcotic drug of his addiction. The narcotic drug administered to an addict suffering withdrawal agonies would relieve those agonies exactly in proportion to the amounts of drug administered. Each addict had a constant sequence of symptoms attending the so-called "dying-out" of the drug. These symptoms were relieved in constant reverse sequence by the administration of the drug, and in exact proportion to the amount of drug administered. A small amount of drug would relieve the symptoms last appearing; another insufficient amount would relieve another proportion of the withdrawal signs, and so on until the narcotic drug administered balanced in amount the extent of the addict's deprivation. This was almost mathematical in its working and an addict after a few trials could tell within a very close margin just how much morphine had been administered to him by the extent to which it relieved his withdrawal signs. In speaking of the essential mechanism of narcotic drug addiction, physical results must be explained by physical cause and Dr. Bishop advanced his own solution. Tolerance of and immunity to the toxic effects of narcotic drugs were primary and striking characteristics in the development of addiction. An antitoxin and antidotal substance was the recognized mechanism of production in most diseases admittedly developing these characteristics. He, therefore, advanced the hypothesis that an antidotal substance was manufactured by the body as a protection against the poisonous effects of narcotic drugs constantly administered. A hypothetical antidotal toxic substance manufactured by the body as a protection against the toxic effect of continued overdosage with a narcotic drug would, therefore, explain the well-known development of tolerance and immunity in these cases, and would account for the violent physical withdrawal signs. In a word it would explain the disease fundamentals on a definite physical basis. Such an hypothesis would explain the stages of development of addiction above noted. This theory had been adopted by Dercum and other writers. Right or wrong, purely hypothetical as it was, it at least offered a working basis in physical explanation of definite disease manifestations. Narcotic drugs had the power to inhibit body function and they markedly arrested metabolic processes. They inhibited glandular activity. They inhibited unstriped muscle action and hence peristalsis. They, therefore, caused a slowing-up of glandular and intestinal elimination. This resulted in an accumulation of drugs, or of products of the drugs, and a constant residue exisiting in the body. It was this constant residue to which the body must become tolerant by the development of some mechanism for its protection. It was to the element of inhibition of function that they must look for an explanation of what was by far the most important element in the immediate picture presented by most of the individual cases. He referred to autotoxemia. Upon the extent of inhibition of function and autointoxication, therefore, depended the predominating manifestations in the individual case and the measure of disease in the individual sufferer. They contributed the immediate and compelling indications for rational therapeutic endeavor. They, to a great extent, determined circulatory efficiency and physical reaction. They largely controlled physical tone and physical reaction. With inhibition and autointoxication eliminated or reduced to a minimum, the patient could go through many years an apparently normal man, well-nourished, reactive, in good physical tone, mentally and physically sane. He showed practically nothing abnormal as long as he got properly administered his accustomed narcotic drug and in the amount of its minimum need. Treatment depended

upon rational appreciation and measure of narcotic drug need, and of inhibition of function and autotoxemia in their varying and interacting manifestations and symptomatology. It resolved itself into the rational care of the individual case. Supply the drug of body need as long as it was necessary, and in such amounts as were useful in the maintenance of body function. Do this at sufficiently wide intervals of administration to minimize drug inhibitory effect. Combat inhibition of function by strychnine in such doses as the toxic case required. Combat autotoxemia by intelligent elimination, based on individual reaction, being very careful not to exhaust eliminative ability by depleting overadministration of ill-advised and illy-timed catharsis. When the patient was in a condition of satisfactory reaction, sweep out the residue of drug and autotoxins, easing the removal reaction by the administration of an alkaloid of the belladonna group, preferably hyoscine or scopolamine. Administer the narcotic drug to your patient in sufficient quantities to meet indications and do not try to reduce the amount of the drug until you have reduced the extent of physical need for the drug. General tone and metabolic efficiency and adequate elimination were of far more importance than the mere fact that the patient was taking a smaller amount of the drug.

Dr. George E. Petty of Memphis, Tenn., said that if such a classical paper had been available sixteen years ago when he took up the study of the subject he would have been saved many anxious months of groping in the dark, seeking to find some rational interpretation of the varied phenomena presented by narcotic drug users when deprived of their normal drug supply. The literature of this subject, until recently, had been the most disappointing of any medical subject with which he was acquainted. At the time he took up the study of this subject he had before him a concrete example, a case in which he knew no element of vice entered into the formation of the addiction or into the continuation thereof. This early led him to reject the vice theory, and a little experience also soon led him to see that the condition was not a neurosis. Reaching these conclusions enabled him to approach the subject with a much less clouded field of vision, but did not at once furnish an answer to the burning questions: "What was the matter with the patient?" "What pathological conditions underlay the symptoms presented, and what could be done for their relief?" The fact that the patient was using a narcotic drug was dismissed from immediate consideration and an examination of the patient was undertaken with the purpose of ascertaining the condition of every organ and function of the body. This examination revealed marked functional derangement, especially of the gastrointestinal tract; her breath was foul, the tongue was coated, her bowels were constipated, the liver was enlarged, the portal system was engorged, the skin was dry and sallow, in fact there was every evidence of profound intestinal and auto-intoxication. It was then asked, "If this patient were not using a narcotic drug, what would be the indications in treatment?" There could be but one answer, "Cleanse the system from toxic matter!" It was decided to treat that part of the ailment according to the general principles of medicine. Purgatives of composition and dosage usually employed were given, but the results were not satisfactory. After repeated failure to successfully carry out even this step in a rational treatment, the cause of these failures began to dawn upon him. Intestinal atony and not sufficient secretions accounted for the failure to secure free purgation. The problem he was confronted with was that of restoring normal or efficient intestinal motion in spite of the restraining effect of the opiate. Strychnine was given for the purpose of exciting intestinal motion by direct stimulation of the motor centers. With this function restored it was found that the purgatives, which failed to act before, now acted promptly and efficiently as if the patient were not addicted to a narcotic. The reader was able to clear the system of his patient of toxic matter; when this was done, not more than one-quarter of the quantity of the opiate formerly used was necessary to meet the demands of the patient and keep her in comfort. A few days later the last of the opiate was withdrawn, but to his surprise the suffering, formerly so severe, did not occur. The employment of this plan of treatment in a few cases led him to place the proper estimate on the toxic element as a pathological factor in these cases, but about 150 cases were treated before he reached the conclusion that the essential pathology of narcotic drug addiction was toxemia, the toxins being of drug, intestinal, and autochthonous origin. This conclusion was reached about fourteen years ago and he felt sure that it would stand the test of time. For a number of years he had held that narcotic drug addiction was the most certainly and readily curable of all the chronic ailments. Narcotic drug addiction was, essentially, neither a neurosis, a psychosis, or a vice, but was a systemic disease, functional it might be true, but a disease nevertheless, one which yielded promptly and completely to rational treatment based upon well-established physiological laws.

Dr. Charles A. Rosenwasser said that Dr. Bishop had shown that narcotic drug addiction was a very complex condition, and this being so it was absurd to claim that any drug or combination of drugs had any specific properties in its treatment. For this reason any institution which claimed to cure narcotic drug addiction by the use of certain alleged specific remedies was to be condemned.

Dr. Bishop, in closing, said that the main point to be kept in mind was that these people, the narcotic addicts, were sick and sick of a definite disease. This disease was complex and widely variable in the individual cases. Fundamental disease could not be cured or handled by mental, moral or psychictrical approach. There was not and never would be any specific routine treatment applicable to any complex and variable disease condition. Narcotic drug addiction was a definite, curable disease in its fundamentals and should be so regarded and so treated.

NEW YORK NEUROLOGICAL SOCIETY AND NEUROLOGICAL SECTION OF THE N. Y. ACADEMY OF MEDICINE.

Combined Meeting, Held on November 10, 1914.

Dr. Smith Ely Jelliffe, President of the N. Y. Neurological Society.

Dr. I. Strauss, Chairman of the Neurological Section of the N. Y. Academy of Medicine.

Scleroderma, with Contractions.—Dr. S. P. Goodhart presented an unmarried girl, 24 years old, a Hungarian Jewess, whose family and previous personal history showed nothing of interest. Her present illness began about nine years ago, when she noticed a swelling of the toes, followed by increasing stiffness of the toes and knees. About the same time she also complained of a feeling of coldness and weakness in the lower extremities, with paroxysmal attacks of whiteness of the skin of the hands, together with pain and tingling. With the disappearance of the blanching, the hands would become congested and then cyanotic. Because of increasing weakness the hands lost in function, and flexure contractures soon appeared. These symptoms for a time increased in severity and then remained stationary. About five and a half years ago the patient noticed pigmentation of the chest and a peculiar stiffness of the face, so that she was scarcely able to open her mouth. Some months later there was some improvement in the power of moving the knees and toes. When the weather was cold she had noticed a numbness of the nose and tongue, but not of the lips nor ears. The legs could be separated for a distance of only about six inches at the knees, due apparently to fixation at the hip joints. Over the feet there was a hide-bound condition, but less marked than in the hands, which presented the typical appearance of a pronounced sclerodactyle. The face was distinctly masked in character, with all lines obliterated: the palpebral fissures were wide, giving a strange expression to the eyes. The margins of the lips were very narrow, and the mouth was held stiffly and always partially open, giving rise to a mummified expression. The nose was narrow and angular. The ears, which were indurated, thin and blanched, were held rigidly down. The mucous membrane of the mouth was becoming involved, showing some induration to the touch. The scalp showed no abnormality. The mammæ were fairly well developed. Trophic disturbances were well marked over the small joints of the fingers and toes. The skin showed glossiness as well as the pigmentation. Many scars were present, due to previous ulcers of the fingers and toes. Sensation: A few years ago there was a slight but manifest diminution to painful stimuli from the finger-tips up to the wrists: this was also true of the feet and ankles. At present, no sen-

sory changes were found excepting that there was a lack of proper appreciation of hot and cold stimuli. Dr. Goodhart said the interesting features in this case were the initial symptoms, which pointed strongly to Raynaud's disease; indeed, that was the original diagnosis and the one with which the patient was discharged from the Harlem Hospital. Further, the case offered a recognition of the various stages of the disease, so far as it affected the soft tissues, namely: oedema, induration and atrophy, and the characteristic cutaneous pigmentation. The restriction in the movements of the joints was by no means entirely due to the hide-bound condition; there were true changes in the joints giving rise to ankylosis. The hip joints were so restricted by the intra-articular pathological process as to afford very little movement to these joints. There was doubtless rarefaction and absorption of osseous tissue in some of the larger joints analogous to the atrophic process of the subcutaneous tissue. There had been periods of marked improvement in the condition of this patient, and for a time the administration of thyroid extract seemed to be responsible for it. The initial symptoms affecting the periphery of the extremities and suggesting Raynaud's disease, together with the dissociated sensory changes, indicated a trophoneurosis. An interesting symptom in this case was the beginning involvement of the mucous membrane of the mouth. The vaginal mucosa had not been examined. Dr. Goodhart said he did not believe that the pigmentation in this case was really indicative of adrenal involvement, there being no other symptom of Addison's symptom-complex.

Dr. WALTER TIMME thought this condition was one of generalized connective tissue hyperplasia, of which the scleroderma was only a single manifestation. This connective tissue hyperplasia, in turn, was secondary, as a rule, to a disturbance of the sympathetic and autonomic nerve supply. In most of these cases of scleroderma we get the history of an antecedent high grade sympathicotonia, and as this increases we begin to get the tissue hyperplasia, sometimes in the muscles and joints, and occasionally in the thyroid, the hypophysis cerebri and blood vessels. We have an overactive sympathetic and an under-active autonomic system. In the end, it probably resolves itself into a question of disturbance of the internal secretions, and from a therapeutic standpoint we had seen some benefit from the use of various internal secretions. These must be brought to bear upon the particular symptom that was in the foreground, and it required a good deal of application and patience to arrive at any result. Many of the symptoms of these patients, such as the lack of perspiration, the occasional rapid pulse, etc., went to prove the contention that the condition was due to a disturbance of balance between the sympathetic and autonomic nervous systems. In reply to a question as to whether he regarded the lesion in the case shown by Dr. Goodhart as cortical or sub-cortical, Dr. Timme said it had been shown that the ablation of one of the hemispheres gave rise to certain sympathetic manifestations, but just what part of the hemisphere was involved we did not know. The highest level to which they had been traced thus far was in the region subjacent to the corpora quadrigemina, to the hypothalamus, to the stalk of the hypophysis and some of the centers of the vagus. Manifestations of the autonomic system had been found in hypophysis stimulation.

Dr. GOODHART, replying to Dr. Timme, said that in spite of the lack of pathological evidence, the clinical evidence seemed to be very striking of a higher center, probably about the motor area.

Dystonia Musculorum Progressiva.—Dr. H. CLIMENKO reported this case (see Vol. 26, No. 24, p. 1000).

Dr. C. C. BELING of Newark, N. J., said that at a meeting of this society some time ago he presented a case bearing some resemblance to that shown by Dr. Climenko. That was the only case he had seen. The one shown to-night seemed to be in a rather earlier stage.

Dr. I. ABRAHAMSON said he showed a case of dystonia musculorum progressiva at a meeting of this society about two years ago, and since then he had seen two additional cases. In the case he had presented the disease had previously developed in the patient's sister, and these were the only instances on record, so far as he knew, of two cases in the same family. Oppenheim, in his description of this disease, spoke of its usually beginning in the hand, the child noticing that it could only write with difficulty, the symptoms later extending to the leg, etc. In a typical case which came under his observation about a week ago at the Montefiore Home, the patient, a girl, had hypertrophy of the lower extremity which was affected by the dystonia, and from time to time there were cramplike spasms in these muscles. This hypertrophy and hypertonicity is also observed in Thomsen's disease. The case shown by Dr. Climenko, Dr. Abrahamson said, seemed to present a typical case of dystonia musculorum progressiva.

Dr. I STRAUSS said that in one case that came under his observation, in addition to the hypertonicity, there was reaction of degeneration in the muscles of one leg. That patient died. No autopsy was obtained. The condition began in one arm following a trauma, and the first appearance of the tremor was in the injured arm. From here it spread over the entire body, and the child was in a constant state of spasm, so that repeated doses of hyoscine were required to keep it quiet. In this case the dystonia and lordosis were extreme.

DR. WILLIAM M. LESZYNSKY said that the case of dystonia musculorum progressiva which he showed at a meeting of the New York Neurological Society about nine years ago was the first case of the kind presented in this country. That patient had been subjected to various forms of treatment, including tendon cutting to relax the muscular spasm, etc. At a later date he was again shown at a meeting of the society by Drs. Hunt and Kruna. Dr. Leszynsky said that at the time he presented the patient no diagnosis was made. There was no scoliosis, but the boy moved about on all-fours, with constant peculiar and fantastic movements. He improved for a time, but subsequently his symptoms became exaggerated.

Dr. CLIMENKO, in closing, thought that Oppenheim emphasized the fact that there were no organic muscular changes, hypertrophy nor atrophy, and that the characteristic marks of the disorder were hypertonia and atonia: these he regarded as the only cases that should come under the category of dystonia. Other writers on this subject failed to agree with Oppenheim and cited cases in which atony was lacking.

Pilous Cerebral Adiposity.—Dr. WALTER MAX KRAUS, in showing this case, said that many instances of genital dystrophy associated with obesity had been described since Froelich first separated the syndrome from the general class of obesities, but he had not found any account of a class of cases complicated by an anomalous condition such as was presented in this case; namely, a marked increase of the body hair, accompanied by a lack of the dry skin characteristic of the classical Froelich syndrome. This patient, in the service of Dr. Alexander Lambert, in the medical wards of Bellevue Hospital, was a white man, 31 years old; a watchman by occupation. His father was living and an alcoholic; his mother died of nephritis following childbirth. One brother died in infancy of unknown cause; one sister was living and well. Otherwise the family history was negative. The patient had been married since 1906. His wife had had one miscarriage and four normally born children; three of these had died in infancy, one of meningitis, the others of unknown causes. The living child was two years old and well. The patient had been accustomed to drink from five to seven glasses of beer daily up to the onset of his present illness in 1910. He smoked moderately. He gave a history of measles, chicken-pox, diphtheria and whooping cough in childhood, and some form of arthritis from the age of 24 (1908) until one year ago. The soles of his feet were sore and later the tissues about the knees became red, swollen, hot and painful. After several of these attacks there was some limitation of motion, but one year ago, after treatment at the Metropolitan Hospital in this city, the patient was cured. Between the ages of three and four years he fell from the fifth story of his residence to the ground, resulting, as he states, in a fracture of the crown of the skull. He was unconscious for about fourteen hours and disabled for six months. From that time until the age of thirteen he was entirely well. Then he began to have attacks of Jacksonian epilepsy, which occurred from three to six times yearly and were not of sufficient severity to cause the patient to either tell his parents or seek the aid of a physician. At the age of twenty-five, a little over twelve years after the first attack, the attacks ceased and had not since recurred. Four years ago, at the age of twenty-seven, the patient began to grow fatter. At that time his weight was 150 pounds; in 1912 it had increased to

204 pounds; in 1913 to 263 pounds, and his weight at the present time was 282 pounds. At about the same time as this increase in adipose tissue began the following symptoms made their appearance: his hair began to increase over the trunk and extremities, he felt sleepy, and as time went on he would fall asleep involuntarily in addition to sleeping a good deal voluntarily. In 1910, while driving a large automobile beer-truck, he fell asleep, allowing the truck to run into a saloon. This accident deprived him of his chauffeur's license. These narcoleptic attacks had continued since. The patient's appetite for food, especially meat and carbohydrates, had increased. He also complained of shortness of breath and sweated a good deal. Three and a half years ago he noticed that his penis was smaller and that shortly afterwards his sexual desire grew less until now he had none at all. Dr. Kraus said it was difficult to form any clear conception of the basic cause in this case. A fall on the head at four years of age, followed nine years later by mild Jacksonian epileptic attacks, which lasted thirteen years, led one to believe that some neoplasm was present. The beginning increase in the accumulation of fat two years later pointed to an involvement of the glandular hypophysis, with the probability that in the interval the glandular part was gradually decreasing in power until its limit of safety was overstepped, with the ensuing appearance of the Froelich syndrome, complicated by atypical changes in the skin and blood. The absence of any involvement of the cranial nerves or of a cranial neoplasm made it impossible to settle on any diagnosis other than hypopituitarism. A blood examination showed 6,720,000 red cells; 10,800 white cells; polymorphonuclear neutrophiles, 56 per cent; eosinophiles, 3 per cent; transitionals, 1 per cent; large lymphocytes, 19 per cent; small lymphocytes, 11 per cent; large mononuclears, 10 per cent; hemoglobin, 110 per cent (Sahli). Urine: Albumin ranged from 1 to 6 grams per day during two weeks' observation; usually about 3 grams. No sugar. Many granular casts and a few white blood cells. Carbohydate tolerance: From 100 to 500 grams of dextrose were all without effect in causing glycosuria; 700 grams was followed by only a trace of sugar in the urine. Blood pressure: Systolic, 170 mm.; diastolic, 120 mm. Wassermann negative.

Dr. ABRAHAMSON said that in the wards of Mt. Sinai Hospital they had at the present time a young woman with very similar manifestations to those in the case shown by Dr. Kraus. She gave a history of amenorrhea, hyperidrosis, peculiar skin changes and adiposity; she complained of sleepiness and had a growth of hair on the face and body, but the urine contained sugar and showed, as in Dr. Kraus's case, evidences of an advanced nephritis. A blood count gave 6,100,000 red cells and 10,000 white cells, with 110 per cent of hemoglobin. It was noteworthy that the urine constantly contained a small percentage of sugar. The sugar tolerance was being investigated. The facies looked like a typical one of polycythemia. The moist skin in this case might be attributed to the nephritis as well as the polycythemia, but was most likely a part of the polyglandular disease. As he had not seen the *x*-ray plate he could not report on the findings.

Dr. STRAUSS said that in the case mentioned by Dr. Abrahamson the *x*-ray showed an enlargement of the sella turcica which was enough to be due to a tumor.

Dr. TIMME said that the hypertrichosis present in this case was not quite as generally distributed as had been stated, for upon closer inspection it could be seen that the distribution was radicular in character, and furthermore skipped the areas supplied by the cervical roots, to begin again at the dorsal level. This arrangement corresponds with the position of the cells of the superior spinal sympathetic nucleus, which is non-existent in the cervical region of the cord, and begins at about the first dorsal level. This is rather suggestive, therefore, of sympathetic involvement.

Wilson's Lenticular Degeneration.—Dr. CHARLES E. NAMMACK presented a boy, twenty years old, who was admitted to Bellevue Hospital on June 20, 1914. He had never had any regular occupation. His father died at the age of forty-two of glandular tuberculosis; his mother at about the same age of pulmonary tuberculosis. His parents were not consanguineously related. The mother had seven children, the patient being the last child. Of the seven children, four were living and in good health. One brother died of pulmonary tuberculosis. The patient stated that so far as he knew no one in either branch of the family had a condition similar to his. The family history was negative as to gout, rheumatism, syphilis, alcoholism, or nervous affections. One of his brothers was married and had one child, in good health. There was also a married sister with two children in fair health. This patient attended school until he was unable to stay in the class. He smoked cigarettes and occasionally drank a glass of beer. He had the usual diseases of childhood and at the age of five years he lost his speech and the power of walking, being obliged to creep around, but he was able to go to school at the age of ten, and left six years later, in 4-A grade. He states that he was always near the head of his class and liked to study. He had a bad temper and would get into quarrels with the other boys. He left school at the age of sixteen because his left arm began to shake so that he could not hold objects in it. After he left school he remained at home, occasionally going out with draymen, etc., but he had never had any regular work. The first symptom of the disease occurred when he was six years old, when it was noticed that his left hand trembled considerably and that his right leg slowly turned in, as the patient expressed it. The foot finally got into such a condition that he walked on the side of the foot and had to catch hold of bed-posts, etc., to support himself. He was taken to the family physician, who said that he had St. Vitus dance. There was no history of epileptic fits or periods of unconsciousness. Gradually the tremor of the hand became more aggravated, the condition of the foot became worse, and his speech became so nasal in quality that it was difficult to understand him. When he started to do anything he had to wait a few minutes and then quickly arose; as soon as he got up he would start swaying around and would have to take hold of some support to pull himself along. If he was in the open, without support, he would throw himself forward and drag or slide his feet. After he started walking he got along very well unless he stopped; states he could walk across the Brooklyn bridge provided he did not stop but kept right on. The muscles of the arm and trunk were remarkably well developed. The patient's facial expression was fixed; the mouth was large and drawn, and when walking or doing any form of exercise he protruded his tongue. He understood everything that was said to him and was usually in a jolly mood, although he had a bad temper. His intelligence was about on a par with that of a boy of twelve or thirteen. He was able to dress and to feed himself; only it took him longer. His condition had apparently remained unchanged for several months; at least it did not appear to differ physically or intellectually since the date of his admission on June 20, 1914. The patient was well developed and nourished. His movements were jerky; that is, his head and arms would jerk while his spine became rigid with a functional anterior curvature, with talipes equinovarus of the left side. As he bent forward the right foot was thrown out in an inverted position, and the left foot was drawn by sliding, in the meantime the head, arms and pelvis going through jerky motions. The speech was long and drawling, making it difficult to understand him. Swallowing was normal. The tremor of the hand was coarse. The grip was good; the knee and angle jerks were exaggerated; sensations appeared to be normal. The Wassermann test was negative. There was atrophy of the muscles of the right leg, hip and calf, with compensatory hypertrophy of the other muscles of the body. Dr. Nammack said that when this boy was about ten years old he was treated at the Cornell Dispensary, without diagnosis. About two years later he was under treatment at the Vanderbilt Clinic; diagnosis withheld. When he was admitted to Bellevue Hospital in June, 1914, the case was regarded as a puzzle until Dr. Foster Kennedy called attention to Wilson's article on lenticular degeneration, when it was placed in that category. So far as he was aware, Dr. Nammack said, this was the first case of Wilson's lenticular degeneration to be shown in this city. One case had been reported in Philadelphia.

Dr. FOSTER KENNEDY said that while he was inclined to regard this case as an example of Wilson's lenticular degeneration, he recognized the fact that there was considerable scope for argument in the diagnosis. In several important respects, this case did not absolutely conform with the clinical description given by Wilson in his paper. One was the comparatively slow progress of the disease in this case—its long duration. Then, again, there was the lack of emaciation and pyrexia and the absence of any evidence of liver disease. Of course, it was fair to presume that the len-

ticular nucleus could be diseased without visceral involvement and give rise to a syndrome somewhat dissimilar from that described by Wilson, but as the case stood now, it did not conform in the above particulars with the original description of Wilson's disease, which was regarded by him as a clinical entity, dependent on toxic causes, and the main features of which were involvement of the liver, associated with degeneration of the lenticular nucleus. It was unfortunate that the name adopted by Wilson, *i.e.* progressive lenticular degeneration, did not suggest the presence of concomitant liver disease. Whether or not the liver was cirrhosed in the case shown by Dr. Nammack could not be definitely stated at this stage. In only one of Wilson's cases was there jaundice.

Dr. J. Ramsay Hunt said that he had been very chary in making the diagnosis of Wilson's disease since an experience with a case which had been under observation for a number of years at the Montefiore Home in which the clinical picture was typical of this condition. The progressive rigidity and the terminal symptoms corresponded in almost every particular with Wilson's description of lenticular degeneration. At the autopsy, however, the liver was found to be perfectly normal and careful serial sections of the lenticular nucleus showed no macroscopic lesions. Some histological studies were now being made in this case which were not yet complete. The clinical picture of Wilson's disease, therefore, may be very closely simulated by a clinical type which is probably a juvenile paralysis agitans. In the case presented by Dr. Nammack, the symptoms, which are now of 14 years duration, seemed to have been consecutive to an acute cerebral affection of early childhood. It was not unlikely that the entire clinical picture was simply the result of a polio-encephalitic process in early life, and not a progressive, degenerative condition.

Dr. Smith Ely Jelliffe said that the bilateral character of lenticular degeneration as originally described by Dr. Wilson assumed importance. This patient did not show a bilateral tremor. The patient had athetoid movements of the left upper extremity, and palsy and spasm of the right leg, and the speaker said he was inclined to agree with Dr. Hunt that we had here the results of a polio-encephalitic occurring in youth, with athetosis on one side and spasm on the opposite side. In the cases described by Wilson the tremor was invariably bilateral. In some of the patients which were presented at the meetings of this Society by Dr. Jeliffe, as probable cases of multiple sclerosis with paralysis agitans like syndromes, the possibility of Wilson's degeneration was considered and the relationships to this disease taken up. He thought that the diagnosis of lenticular degeneration could not be successfully maintained in this case on account of the absence of any hepatic involvement, the long duration of the disease, the non-bilaterality of the symptoms, and the doubtful clinical findings.

Dr. Nammack, in closing, said the possibility of an old cerebral hemorrhage, with post-hemiplegic athetosis, was considered in connection with this case, but subsequently rejected. The patient's symptoms had not been noticeably progressive since his admission to the hospital four months ago. As regarded the long duration of the disease in this case, and its bearing upon the possible diagnosis of Wilson's disease, Dr. Nammack said there was considerable difference of opinion among those who had reported cases of lenticular degeneration since Wilson's original description. Wilson divided his cases into two groups, *i.e.* acute and chronic, the duration of the latter averaging four years. Sawyer's case lasted seventeen years, but when Wilson saw this case he threw it out. None of the cases reported in this country entirely agreed with Wilson's description. While this case was somewhat analogous to the juvenile type of paralysis agitans, there was enough difference to separate them clinically.

The Treatment of Syphilis of the Nervous System with Salvarsan in the Frankfurt and Hamburg Clinics.—Dr. F. J. Conzelmann read a paper on this subject in which he described in detail the methods employed in the treatment of syphilis of the nervous system with salvarsan in the two representative clinics in Germany—the Dreyfus clinic at Frankfort and the Nonne's clinic at Hamburg. At the Dreyfus clinic the first idea of salvarsan was conceived, and here the great master Ehrlich visited the clinic, rendered individual supervision and offered suggestions. One was impressed with the well planned and orderly arrangement of the clinic, and the feature that stood out most prominently was that Dreyfus did not treat the patients as merely cases, but as individuals. He first selected the type of the disease; secondly, he gave the intensive treatment of salvarsan and mercury; thirdly, he adapted the dose of salvarsan or mercury to the individual and was guided by the constitutional reaction; and, fourthly, the treatment was continuous, with definite periods of intermission. Ehrlich and Dreyfus preferred old salvarsan to neosalvarsan, and used the latter only on certain indications, especially when a mild, non-irritating action was desired: nevertheless, the initial treatment was frequently begun with neosalvarsan. The concentrated solution of salvarsan was always used, and was prepared as follows: The dose of old or neosalvarsan was dissolved in 35 c.c. of double distilled water; then the sterile sodium hydroxide was added and the solution injected with the syringe directly into the vein. A searching physical examination of the patient preceded every course of treatment with salvarsan: in fact, it determined the final treatment. Patients suffering from syphilitic affections of the nervous system soon after the primary infection were as a rule strong, robust individuals, and could tolerate a much larger dose than those in whom the infection had been present for many years. If the patient suffered from gastric trouble, a thorough stomach analysis was made and the condition treated before giving salvarsan. In patients over 60 years of age, salvarsan was given with a great deal of care. In cases with tuberculosis, chronic heart disease or nephritis, the pros and cons were carefully considered. A course of treatment lasted six or eight weeks, during which time the patient received from three to six grams of old salvarsan, or from four and a half to nine grams of neosalvarsan, with from six to twelve mercurial injections of 0.02 to 0.05 of a 40 per cent. calomel solution, or the same dose of some especially prepared oily solution of mercury. Patients, after receiving a dose of salvarsan intravenously, were kept in bed for twenty-four hours; if at the end of that time there was no feeling of illness nor rise of temperature, they were permitted to get up. Two examinations of the urine weekly were considered imperative. After the physical examination of the patient, which included lumbar puncture and a Wassermann test of the blood and spinal fluid, had been completed, the diagnosis of the stage of the disease was agreed upon, and a carefully planned, systematic course of treatment was begun. The approximate outline of such a course of treatment in early brain syphilis was as follows: A course of mercurial treatment consisting of five injections of 0.02 to 0.05 c.c. of a 40 per cent. calomel solution every third day. If, at the end of this time, the patient showed no febrile reaction to the injections of mercury, the injections of salvarsan were begun. The mercury injections were continued every third day, and a concentrated solution of 0.15 grams of neosalvarsan was injected directly into the vein with a syringe. If this dose produced no reaction, the patient received a second dose of 0.3 grams on the following day: no untoward symptoms developing, he received 0.45 the third day and 0.6 on the fifth day. This was continued every other day until the patient had received from one and a half to two grams of neosalvarsan. Dreyfus began the treatment with old salvarsan, generally starting with a small dose of 0.1 and never going beyond 0.4. The dose was repeated every second day. If at any time during the treatment the patient had a febrile reaction after the injection, the treatment was discontinued and not resumed until the patient was free from fever at least two days. A favorable prognosis was given in early brain syphilis—in fact, a positive cure was promised—to all who returned for re-examination and took the treatment if the physician advised it and considered it imperative. In the majority of cases of late syphilis of the cerebrospinal system the prognosis in the Dreyfus clinic was generally favorable for improvement, but not for cure. In tabes the patients were treated with salvarsan alone for three weeks, giving one injection of salvarsan of 0.1 to 0.2 grams every other day. At the end of that time the treatment was combined with mercury. As a rule, Dreyfus preferred mercurial inunction in cases of tabes, but often used the mercurial salicylate. With this form of treatment the patients improved rapidly, gastric and lancinating pains disappeared and the ataxia and visceral symptoms improved. Tabetic cases were always emphat-

ically advised to take a course of treatment every three months until four courses were taken. In the intraspinous administration of salvarsan, Dreyfus used Gennerich's modification of the Swift-Ellis method. He dissolved 0.15 grams of neosalvarsan in 300 c.c. of sterile salt solution, and of this solution five c.c. were injected intraspinously after the withdrawal of an equal quantity of spinal fluid. His results in initial lues cerebri were very encouraging, while in tabes the results of the intraspinous method of treatment were symptomatic but nevertheless very striking. Dreyfus had no cases of general paresis in his ward. Since February, 1914, Dreyfus had used two new preparations of salvarsan from Ehrlich's laboratory: the one was copper salvarsan, the other sodium salvarsan. Both could readily be dissolved in water and did not entail the manipulation required in the preparation of old salvarsan. The solutions were given in concentrated form directly into the vein with the syringe. With this mode of administration, three or four cases could easily be treated in the course of half an hour. Iin Nonne's clinic at Hamburg, every patient suffering from syphilitic or metasyphilitic disease of the nervous system received a course of mercurial inunctions, irrespective of the stage of the disease. For purposes of treatment Nonne had his tabes cases divided into groups: one group received mercury inunctions, another group mercury inunctions and intravenous injections of salvarsan, a third group mercury inunctions plus intraspinous injections of salvarsan and a fourth group received no treatment whatsoever. In cases of general paralysis he used the mercurial inunctions and intraspinous injections of salvarsan: in cases of cerebral lues he preferred to give mercurial inunctions, with intravenous injections of salvarsan. He employed von Schubert's modification of the Swift-Ellis method. In his tabes cases Nonne got improvement, symptomatically, by the intraspinous method, but in some cases the bladder symptoms were very much worse after the treatment.

Dr. J. F. TERRIBERRY said he had under his observation at the present time a man about 30 with tabes who was so much disturbed by the old-time antisyphilitic treatment that all treatment was discontinued. Under this let-alone method he had remained comparatively free from symptoms during the past year, and excepting for a slight difficulty in locomotion he seemed to be in perfect health. We must not underestimate nature's restorative powers under good hygienic and dietetic conditions.

Dr. CONZELMANN, in reply to a question, said that so many of Nonne's cases of tabes got along well without any treatment aside from rest in bed that Nonne was rather skeptical in regard to the value of the intraspinous injections in cases of tabes.

Persistent Erythema of an Erythromelalgic Type.—G. N. Meachen reports the case of a girl aged 15 years whose ailment was diagnosed as erythema nodosum. For the last two and a half years she was said to have had pain in the legs, relieved by assuming the horizontal position, and the shins were of a purplish-red color. There was no history of actual joint pains, but eighteen months ago she had had pains in her arms like rheumatism. On examination the shins and calves of both legs were of a deep red color, and appeared somewhat tense. The upper and lower margins of these erythematous areas faded gradually into normal skin, and the feet were unaffected. There was no edema. No nodose lesions of any kind were present. The hands were in a condition of erythema perstans. The fingers had never become dead. The heart was normal. A blood count gave the following results: hemoglobin, 75 per cent.; red cells, 3,296,000; white cells, 7,600; small lymphocytes, 28 per cent.; large lymphocytes and transitionals, 7 per cent.; polymorphonuclears, 60 per cent.; eosinophiles, 3 per cent.; mast cells, 2 per cent.; no poikilocytosis; slight anisochromia. The blood coagulation time was seven and a quarter minutes. Though presenting some of the features of erythromelalgia, the condition was not wholly typical of that affection.—*Proceedings of the Royal Society of Medicine.*

Prophylactic Use of Sensitized Vaccines in Puerperal Sepsis.—S. T. Champtaloup believes that in view of the fact that 80 per cent. of the cases of puerperal sepsis are caused by streptococci, it would be well to use a stock sensitized polyvalent streptococcal vaccine as a prophylactic in the face of an epidemic of puerperal infection.

Therapeutic Hints.

A New Treatment for Tuberculous Ulcers.—Ottorino Marroni adds an additional case to the five reported by him before the Tuberculosis Congress in Rome, 1912, in which cases he demonstrated the value of the double salts of mercury and silver in combination with iodine, injected into the interior of tuberculous ulcers. This method of treatment is said to be a definite and a rapid one, being cited as a successful instance of chemotherapy.—*Annali di Medicina Navale e Coloniale.*

The Treatment of Bronchial Asthma.—M. T. Schnirer recommends the following:

℞ Tincture of lobelia,
Wine of antimony, āā, 5 grams.
Anisated solution of ammonia, 1 gram.
S.: During the attack 10 drops may be given every 15 minutes.

Bamberger employs the following mixture:

℞ Tincture of lobelia.
Tincture of digitalis, āā, 5 grams.
Cherry laurel water, 10 grams.
S.: Twenty-five drops may be given every hour during the attack.

Pyridine may be inhaled from a suitable apparatus in doses of 10 to 20 drops.

Kraus has found that one dose of the following powder is effective if administered at the beginning of an attack:

℞ Antipyrine, 0.8 gram.
Caffeine sodium salicylate, 0.2 gram.
—"Taschenbuch der Therapie."

Apomorphine in Bronchitis of Children.—L. Freyberger recommends the following mixture as suitable for a child two years old:

℞ Apomorphine hydrochloride, gr. 1/3.
Dilute hydrochloric acid, ♏ ii.
Syrup of lemon, ♏ xxx.
Distilled water, ad ℥ ii.
M. S.: One teaspoonful every two hours.

The Administration of Paraldehyde.—Whitla employs the following mixture as a hypnotic:

℞ Paraldehyde, ℥ j.
Mucilage of acacia, ℥ ii.
Simple syrup, ℥ ii.
Cinnamon water, ad ℥ ii.
M. S.: To be taken at bedtime.

Treatment of Subacute Alcoholism.—H. A. Hare has found the following prescription of great service in this condition:

℞ Tincture of capsicum, ℥ jss.
Deodorized tincture of opium, ℥ ii.
Spirit of chloroform, ℥ j.
Compound tincture of lavender, ad ℥ jv.
M. S.: Dessertspoonful every four or five hours.

A Powder for Urticaria.—The following is recommended as an effective antipruritic:

℞ Menthol, 0.20 gram.
Camphor, 1 gram.
Magnesium carbonate.
Zinc oxide, āā, 40 grams.
Pulverized talc, 20 grams.
—*Journal de Méd. et de Chir. pratiques.*

Apomorphine in Bronchitis.—L. Freyberger has found the following of service:

℞ Apomorphine hydrochloride, gr. 1/3.
Dilute hydrochloric acid, ♏ij.
Syrup of lemon, ♏xxx.
Distilled water, ad ℥ij.
M. Sig.: ℥j every two hours for a child two years old.
—"Pocket Formulary for the Treatment of Disease in Children."

THE INTOXICATION IMPULSE.*

By ALEXANDER LAMBERT, M.D.,

NEW YORK.

When your committee asked me to read a paper before you on my experience in the treatment of alcohol and drug intoxications, I greatly appreciated the compliment, both because you should wish to hear a paper from me on the subject, and also that after all these years you should care to listen to a subject with which I think most of the profession has grown weary. Their weariness, however, in my opinion, grows from false conceptions of both the causation of the intoxications and of the possibilities of regeneration that each patient will show if properly handled. The old time-honored conceptions have still such hold upon the profession in general that in their busy lives they have neither the inclination nor the time to study the question anew. Morphinism is still looked upon as a vice deliberately acquired, not as a misfortune sometimes accidentally inflicted on the patient by a physician. Alcoholic intoxication is still regarded as a poisoning from which the patient can voluntarily extricate himself, or, failing to do this, must be punished rather than treated medically. Only when physicians must face with some individual in their own practice the many problems that arise with the various forms of Intoxications, do they wish to go into the matter and solve the problems in hand.

My own interest in these problems arose from the necessity of understanding them in order to deal intelligently with my service in Bellevue Hospital, for alcoholism changes the type of clinical manifestations of the various diseases that appear in the service of a large city hospital, and the various drug addictions, until a few years ago, were looked upon as incurable conditions. The sight of the suffering of the drug habitue, his haunting terror lest the drug be taken away from him, his pitiful suffering when it was withdrawn, and the traditional belief in the profession that it was absolutely hopeless to deal with them in any way, combined to awake a keen desire in my mind to search and to see if something could not be found to relieve this misery. Especially did it seem incumbent to do this when I realized how many patients came into the hospital suffering from morphine addiction who had acquired this addiction through legitimate medication, and they were at that time hopelessly condemned to an unhappy and useless existence.

You all are aware that some nine years ago I met a layman, Mr. Towns, who was endeavoring to introduce a treatment for various intoxications. He was sent to me by physicians whose patients he had successfully treated and successfully removed their addiction. At first this gentleman, a business man, could see no reason why, as a business proposition, he could not retain his secret and still have the support of the medical profession in treating patients. When the ethical side of the question was clearly explained to him, he appreciated the standpoint of the medical profession and he appreciated the impossibility of anything but absolute ethical frankness. I did nothing with his treatment until I knew its fullest details, then I used it for some months and published it as soon as possible.

You are all familiar with the details of this treatment. Briefly stated, it consists in the hourly dosage of a mixture of belladonna, hyoscyamus, and xanthoxylum, and at stated intervals vigorous catharsis with some form of mercurial purges. The belladonna mixture is increased or diminished as the patient shows symptoms of the full physiological effect of belladonna. The patient is not cut off suddenly from his drug or his alcohol, but is given the narcotic to which he is addicted at definite intervals, and in diminishing doses, until finally it is withdrawn altogether. The patient is stimulated with various cardiac stimulants as the occasion may require. This treatment is kept up usually from about fifty-six to eighty hours, when a final dose of castor oil is given, the time for the giving of the oil being when the patient is passing green bile.

The basis on which this treatment is conceived is that whether the patient is poisoned from alcohol or drugs, it is necessary to eliminate thoroughly these poisons from the body; in other words, to unpoison him. This the abundant catharsis does, at the same time the belladonna and hyoscyamus acting on the nerve endings of the secretory nerves prevent the excess of action of these nerves following the withdrawal of the habitual narcotic.

This treatment as at present used has been a growth and a development as all such things must be, and the articles published four years ago concerning it do not describe accurately the treatment as carried out to-day. It has been simplified and developed as experience has taught the wisdom of so doing, and these changes I have published. With the experience gained in dealing with these patients both during the medicinal treatment and after they have finished, my ideas concerning the fundamental reasons of men's various intoxications and the wisest way to deal with the individual have also changed and developed. It seemed wise to take the experience gained in the last four years, during which a definite treatment has been used, and see if the results obtained with these patients can help us formulate a broad conception of the causation of the various intoxications in the different ages and stages of a man's life, and consider also what can be done with each individual to solve his problems and rehabilitate him from a diseased and useless

*Read before the College of Physicians and Surgeons, Pittsburgh, December 10, 1914.

personality into a healthy and useful member of the community.

Let us first consider, in figures, the results of the treatment to which I have just referred. Of 1019 patients treated for alcoholism there have been 105 known relapses, that is, 10 per cent. Of these several have relapsed once or twice, but are now hard-working, sober members of the community. Double the number of known relapses to give due weight for those who may have relapsed unknown to us, and even counting those patients as relapses who have relapsed but have since successfully been brought to sobriety, and there still remains 80 per cent. of successes and 20 per cent. of relapses.

Of 345 morphinists there have been 29, or 8.4 per cent. relapses. Again doubling the known number gives 17 per cent. relapses and 83 per cent. successes. This doubling of the patients that have returned for treatment is purely arbitrary, but it seems the fairest method of giving a conservative statement of the percentage of patients that, with this treatment, one may be justified in expecting to remain free from their addiction.

After the medical treatment has been finished the real solution of the problems begins. There is no question but that these patients should be taken and built up by vigorous physical exertion as quickly and as completely as their age and blood vessels permit. This, in my experience, is best accomplished by sending them to some physical trainer where they can go into strict training and acquire the habit of existing without resorting to their narcotic, and with a body in good condition have no physical excuse to turn again to their indulgence. They also learn to resist and not to do as they formerly have done, turning to their narcotic because of every increased joy or every slight annoying factor in their lives.

Let us consider then what is the propelling motive which will force men at times against their will, against two of the strongest primeval motives of their existence, those of self-preservation and self-interest, to indulge in their intoxications which they know will bring about their destruction and their economic ruin. What is this intoxication impulse?

It is not a development of modern times. It cannot be rightly claimed that it is a recent desire in man to ease the pain of an overstrained existence. The memory of man goeth not back to the time when alcohol was not used and used to excess. The oldest literature we have—Sanscrit, Hebrew, Chinese—all describe religious ceremonies in which wine and the excessive indulgence in it were a noticeable feature. Dr. White of Washington, some years ago, summed up the use of alcohol by saying that man had always used some substance to increase the celebration of his joys and to cut the keen edge of his sorrow, and alcohol had been most often used for this purpose. Partridge* in a recent book expands fully these ideas and draws attention to the fact that alcohol, in its uses at social functions, in its use as a ceremonial drink on all solemn occasions, in the time when all men were savage, was a great civilizing aid in allaying the mutual suspicion of men and in enlarging their social consciousness and increasing their willingness to make treaties and friendly pacts together that feuds and wars between tribes or individuals might be forgotten. The peculiar action of alcohol—that of intensifying and expanding the sense of personality—explains its use among the vigorous and developing races, and it was used as an expression of their expanding growth. Among the savages alcohol was used to bring them out of the hard reality of their existence and its use caused them to believe that it contained some divine essence with which they could become disassociated from their present existence and commune more fully with their spirit world. Hence it was among savages that their religious ceremonials always had some form of alcoholic indulgence and among some peoples only the men were permitted to indulge.

As civilization developed drinking became more of a social custom and more interwoven with the daily life and less confined to religious ceremonial functions. Partridge well points out that it is not an accident that the Greek conception of Bacchus was at first that of a youth in the exuberance of his early manhood and that the great bacchanalian festivals of that nation were in the early vigor of their civilization just previous to their greatest development in arms, philosophy and art. The later excesses of older civilizations, such as the excessive debauchery depicted by Juvenal in Imperial Rome, are undoubtedly an expression of a decaying race trying to forget the tedium of life and its waning powers.

Past racial development of a race and its decay can often be seen in the individuals of the race as they develop from childhood to old age. It would seem, therefore, that we should find an expression in the individuals of to-day in their actions toward alcohol and their reaction to the impulses leading to intoxication which shows the development and racial use of alcohol in the past. Looked at from this standpoint, we will see the intoxication impulse as an expression of the social instinct of an individual, that it is the expression of vigorous youth straining to enjoy the teeming abundance of sensations. Later it is a means to stimulate a belief that the waning youth can still be retained or it is the means with which the still further waning of the powers may be forgotten. This is not offered as an excuse for intoxication, but rather as an explanation of the impulse inherent in the race that, uncontrolled, drives the individual on and overpowers often the instincts of self-preservation and self-interest.

There is no question but that the reasons for excessive drinking in youth are different from those of the late twenties and early thirties and still different from those of the forties and later life. In early manhood, in the early twenties, excessive drinking, such as is often seen in college students and in youths of that age, does not necessarily mean a weak personality or inability to exert self-control. We see too many who, after a short period of intoxication in which they attempt to celebrate their increased joy in life and to obtain a fuller expression of the intensity of their experiences, cease altogether and never again in later life indulge to excess. Others, however, of less vigorous personality, whom we usually classify as possessed of weaker wills, persist too long in their alcoholic poisoning and develop a diminished resistance from which they never free themselves. The dangers and injury of these youthful intoxications are that they poison a developing organism and develop a lack of self-control within the individual. It comes at a time when the outer control of the home is being relaxed and the inner control of the individual is being developed, and the danger is that the inner

*"The Psychology of Intemperance."

control will be weakened and fail to develop and a weak and poisoned personality result.

The social side of intoxication is the causation of the next stage in the late twenties and early thirties. It is the period of full vigor of early manhood. It corresponds to the time when our savage forefathers expected a man to uphold his end at the feast as well as he had held it up in the battle, and to-day, during these years of a man's life, we find the greatest difficulty when alcohol is beginning to poison his personality in persuading a man to cease the indulgence that is doing him harm, because he feels that he is unwilling to acknowledge to himself that there is something in life he cannot do and he feels that the social requirements among his fellows are such that he shall be able to drink as much as any other man. It is difficult for the weaker ones in life to realize that it requires greater strength of character to refuse to do that which is injurious than to endeavor to keep up with those who are stronger. When a man has reached middle life, after forty, the causes which lead to intoxication are those which are found in the narcotic effects of alcohol rather than in the stimulation and expansion of his ego. He no longer becomes drunk because he happens to be drinking with his friends, but he deliberately drinks that he may become drunk and forget both himself and friends and all existence. These reasons, it seems to me, explain the great unexpressed motives of the great mass of humanity that drinks to excess without any particular reason. They express the unknown impulses at the various times of life. We must further remember that alcohol produces the insidious narcotic effects that, when persisted in, generate the desire for more and cannot be broken away from without the painful symptoms of withdrawal and deprivation. Hence in all those who are naturally of weak self-control, in whom the power of control has not been taught or developed, or in whom it has been lost through alcoholic poisoning, the toxic mental perversion due to the alcohol may be stronger than the social impulses or the desire for the narcotic effects, and will be the governing force to continue their alcoholic excesses.

One meets many exceptions to this general rule. Women only in a small number drink to excess through social exigencies. The vast majority that drink, however, do so for the narcotic effect. They wish to obliterate something which they do not wish to or cannot face in consciousness. Often, moreover, after struggling against a desire to drink and bring forgetfulness, they will in their desperation and weariness drink that they may forget the struggle and cease to remember both the dreaded memory and their struggle to forget it.

Another cause of alcoholic indulgence more common in women than in men is the inability to face the harsh realities of life without seeking periods of forgetfulness. Women are more prone to live in day dreams of their own weaving in their endeavor to live in a world they prefer which does not contain the harshness which the realities of life bring to them, and when real life seems too hard they will drink that they may live in their dream consciousness. This, in some cases, goes so far that the alcohol is taken to produce the real dissociation of consciousness so that as long as they are indulging, while they may appear rational and natural, they are really living in a dream consciousness separated from and oblivious to their real waking consciousness. In this they forget their hurt feelings, the sensation of being misunderstood and the unhappiness and disappointments which may be in their lives. From its very nature this is more often an occurrence among the women whose indulgences are periodic. Often the moving factor which drives a woman to alcoholic excess is unknown to her waking consciousness, and is translated in her mind only as an intense fear or an intense desire for alcoholic narcosis. It may be simply the expression of the desire for something through indulgence in which she knows she is able to forget. When the real reason has been found by psychological analysis her alcoholic indulgence will often automatically cease. This retention of unconscious mental remnants of former periods of existence is not uncommon and is not in itself a pathological condition. These remnants are disturbing factors to the mind because they cannot consciously be brought up from the unconscious into the waking consciousness, or if so brought up, they have lost their purpose and meaning in the present existence of the patient. Sidis* explains this condition as pathological "just because they have no purpose, no meaning in the life of the patient." Often they are memories which stand in such contrast to the present existence that the patient turns to alcohol to forget the present. All these hidden mental remnants which recognized or unrecognized so strongly influence human psychology are not confined to Freud's conception that all motives and relations of existence are under sexual domination. Such a conception of human psychopathology is as distorted and perverted as the sexual perversions it endeavors to explain.

There is a large class of men whose individual problems driving them to narcotic forgetfulness occur only in those possessed of sensitive natures: men who from their early youth have harbored feelings that have been hurt by being misunderstood, have been hurt by feeling that in some way they were not the same as their average boyish companions, and therefore inferior. The sense of inferiority, and the struggle against it as they felt handicapped, the hurt feeling of being misunderstood and carrying a burning sense of injustice, is often the unknown motive power that drives a great many men to irregular sprees. Often, because of the failure to resist the intoxication impulse, there unconsciously becomes attached to this unknown mental complex, which has developed from boyhood, a sense of sin and shame which further drives them to alcohol to obtain its narcotic effects. Each one of these problems has to be unraveled as an individual snarl, and although the number is large, these patients must be not handled in masses but separately handled with a very personal individual interest.

The last four years have forced upon me the belief that the majority of periodic drinkers who are endeavoring hopelessly to cease their periodic sprees are really cases of chronic tobacco poisoning. This is seen more frequently among the incessant cigarette smokers than among those who usually smoke a pipe or cigars. It is seen most commonly among those who always inhale their tobacco smoke. Lauder-Brunton mentions the fact that drugs are absorbed by the tracheal mucous membrane as quickly as by subcutaneous injections. Small wonder is it then that the effect of the pyridine and collidin, and other substances contained in tobacco smoke, is quickly felt by those who inhale. The ease with which cigarettes can be smoked, the un-

*Sidis: "Symptomatology, Psychognosis and Diagnosis of Psychopathic Diseases."

versality of the habit, and the accepted permission that a cigarette can be smoked often where a pipe or a cigar cannot, add to the frequency of the cigarette indulgence. Tobacco at first is used to soothe the nerves, and is taken for its soothing effect. In the early stages it slightly quickens the circulation and thus increases cerebral action. It, therefore, helps in mental rapidity in the early stages of moderate indulgence. Soon it is the accepted panacea for any worry or disturbance of the equilibrium of daily life. Then it is soon necessary to have a certain number of cigarettes that a certain amount of the narcotic may be absorbed to smooth out the daily existence. In this stage of tobacco poisoning the lotos eating contentment and mental inertia are evident and further overindulgence brings on a nervousness which, in the beginning, a very little more indulgence in tobacco will allay. Soon, however, the more tobacco that is smoked and the more that is inhaled, the greater is the nervousness. It has then ceased to produce its narcotic effect and is producing its chronic poisoning. The individual therefore turns to something that he knows will have a narcotic effect and quiet his overwrought nerves. This he knows alcohol will do, and in these individuals the first drink of alcohol leaves them not sober and starts in them its narcotic craving which drives them on to the full expression of their spree. As they sober up they cease for a few days both smoking and drinking, and as soon as they are over the spree they begin to smoke again, and the vicious cycle is sooner or later completed.

As I said above, in my own experience I am firmly convinced that this double narcotic poisoning explains the majority of the periodic drinkers of to-day. If these patients are made to cease their smoking their drinking ceases automatically. The periodic wishes to keep away from it. He does not enjoy his spree; it is taken against his better judgment and against his will and desire. It is the expression of an uncontrollable poisoning. If he does not cease his smoking he continues both to smoke and to drink, and the only way to break successfully the vicious circle is by the cessation of his smoking.

There are other periodic alcoholics whose debauches express a recurrent manic depressive condition, and the alcoholic indulgence is but the symptom of an uncontrolled manic desire to run amuck. These often begin with a sexual outburst, the alcoholic indulgence being secondary. The opinion so often expressed that periodic alcoholism is an expression of an epileptic explosion may be true in a few instances. In the last four years I have seen two patients who made me think that this might be so, but only two in one thousand is not a large percentage, and both these individuals had received head injuries so that an expression of their spree was more like the expression of the Jacksonian epilepsy than of the so-called idiopathic. Many of these so-called epileptic explosions will be found in the real manic depressive class or most frequently in the plain tobacco group.

Turning now to that large group of intoxications and poisonings produced by opium and its alkaloids and cocaine do we find the same type of intoxication impulses governing humanity in their addiction to these drugs? It seems to me more than a mere curious coincidence that we do find a very similar condition in the choice of the drug used and the usual time of life when the addiction is begun and the purposes for which the separate drugs are chosen. Cocaine, and recently heroin, are the drugs of the young developing organism seeking to increase its sensations and enjoy life more abundantly and possessing the same curious sense of expanding and intensified ego that alcohol possesses in the early stages of its intoxication. Cocaine as a habit or addiction was first used to spur on a flagging or worn-out body or mind. Many physicians drifted into this habit in the endeavor to tide over long stretches of overwork; others used it as a quick stimulant to relieve the overindulgence of alcohol and other excesses. Under this tremendous stimulus, the young criminals and the gangsters soon found that they were possessed of greater self-confidence, they were convinced that all they attempted would be successful, and that all they desired would surely come to pass. It gave their bodies a greater muscular strength and a heightening and quickening of the reflexes. It gave their minds more courage and greater alertness, and deeper cunning. Small wonder, then, it became universally used both as a means to increase their reckless daring and to enable them to outwit those opposed to them. Centuries ago Peruvian Indians had shown the tremendous increase of endurance that this drug gave to its users, and the criminals and those using it found that under its stimulation they could tirelessly go on almost unlimited hours without sleep and without rest. The laws of action and reaction that to every action there is a contrary and equal reaction forced before long even this group of individuals to realize that in the end the day of reckoning of mental and bodily destruction from cocaine scarcely paid for the short time in which the stimulation of cocaine seemed to place them mentally and bodily above their fellows. The strict enforcement of the laws against cocaine and the discovery by the cocaine habitue that heroin gave the same expansive sense in his personality, gave the same sense of heightened cunning and mental confidence, gave the same sense of bodily vigor, and lasting longer, and lacking the tremendous intensity was not followed by so great a reaction, has turned the majority of cocaine users into heroin habitues. Being three times stronger than morphine, easily absorbed through the nasal mucous membrane as snuff, of comparatively recent discovery, its peculiar effects being little known, hence less restricted by law, and more easily obtained, heroin has become the ideal drug of the criminal and the "tough" young person of both sexes to use in appallingly increasing numbers in our great cities.

Opium smoking and morphine, the former indulgences of the underworld, gave a contented freedom from care and worries that their lives might bring to them. These endowed them with sly and reckless cunning, but they did not give the recklessness and the daring and the increased muscular activity that cocaine and heroin give. These did not give them in their youth the sense of expansive personality, and small wonder is it that the morphine and opium should be discarded for the heroin and the cocaine.

The deterioration under cocaine and heroin is more rapid than under the other alkaloids of opium. Cocaine rapidly destroys what moral sense there may be in any given individual, and if alcohol is added to the cocaine or heroin addiction, the degeneration of moral sense and of personality is exceedingly rapid and exceedingly intense. The impulses leading to the addiction of codeine, morphine and opium arise from the desire for narcotic

forgetfulness rather than for a stimulation of personality. The smoking of opium has a social side to it, and in the East it is used socially as Western nations use tobacco. But even the smoking of opium is often used to ease the weariness of life, not that it always brings about pleasant, happy dreams which tradition has painted, but it does bring about the freedom from care and a happy, dreamy, contented existence and an indifference to the worries of life that gives relief to wearied souls.

The desire for relief of pain, mental or physical, the desire to blunt unbearable sorrow, and the desire to be able to forget, are the impulses which lead humanity into these addictions. Codeine, morphine, and opium addictions belong, therefore, to the years of life after youth is past, and we usually so find them. In recent years it is astonishing to realize how great a part, in well-to-do classes, legitimate medication plays in the formation of morphine and opium addiction. Lichtenstein,* in a recent article, says that in 1,000 cases in the New York City Prison only 2 per cent. acquired their habit in this way. But in his set of cases it is evident that the heroin and cocaine addict were present in large numbers. That even 2 per cent. should be found drifting into the city prisons among the criminals and the gangsters shows that even in the city prisons a small but persistent percentage owe their addiction to medical treatment. In my own private practice the percentage which have acquired their morphine and opium addiction through medication is as high as 80 per cent. Twenty-five years ago, when an interne in Bellevue Hospital, I was struck by the number of unfortunate women who came into the hospital suffering from morphinism following surgical operations. Antiseptic surgery was then not a decade old, and surgeons were only beginning then to learn of the dangers of the morphine habit following the giving of this drug to relieve the pain after operation. Since the technique of surgery has improved, morphine addiction under the surgeon's hands has greatly diminished, and to-day it is in the hands of the practicing physician that the danger lies. To relieve various pains, to relieve insomnia, and the tendency to treat a symptom as a disease and relieve a symptom alone when the symptom is that of pain and suffering, is the cause of such a high proportion of morphine addicts acquiring it through legitimate medication.

It is an almost universal custom to regard the habitual taking of morphine as a vice showing viciousness and depravity, no matter from what cause the addiction may have been acquired, whether taken up voluntarily or acquired unwittingly. It is looked upon as an expression of moral degeneracy, and those afflicted with this habit feel the humiliation and the stigma far more than is usually realized. In the young criminals that acquire it it is but a symptom of their low standard of morals, and adds but little to their depravity, although it may intensify that which they already possess. But to those who have taken it up as a means of surcease of sorrow or who have found themselves in its clutches before they realized that the medication they were taking was thus leading them on, it cannot be put down as a sign of depravity; it surely is under these conditions a great misfortune but not a vice. Without medical assistance, without the proper care, these unfortunate creatures cannot free themselves from the clutch of these drugs. They cannot bear the withdrawal pains and the suffering that deprivation brings on. It is more than we should ask human beings to endure to take these narcotic drugs away from them and not properly care for them in the process.

When once thoroughly poisoned and when the personality has become degenerated, morphinists are inaccurate, their memory is poor, their observations are dulled, they are self-centered and selfish and indifferent to their environment; hence one cannot expect them to react in a normal way and be either accurate or truthful even in ordinary matters. But until this degeneration of personality has occurred, with the exception of trying to hide his habit and about his drug, the morphinist is not a worse liar than his ordinary acquaintances who are not addicted to the drug. I may have had greater good fortune among my morphine patients or greater misfortune among my acquaintances in ordinary life, but I have not found my morphine patients, except concerning their drug and their habit, any more untruthful than my acquaintances. The living horror of the morphinist is that he will be deprived of his drug, and he will lie, steal or commit any crime to obtain his drug when once deprived of it, and in the throes of such frightful suffering that such deprivation brings on. I have cared for individuals in the hospital who were brought in suffering from actual physical starvation and who had thirty or forty dollars in the bank which they did not dare to use for food, but kept to supply themselves with morphine. They were willing to die of starvation and cut its pangs with morphine, but they could not face the horror of the inability to obtain their drug. If the majority of morphinists are relieved from the fear of the deprivation of their drug, in ordinary every-day matters they are as truthful as the average person, and as reliable. This view, which goes against the teaching of the profession, and which goes against my former belief, has developed from my experience of the last few years, and of its accuracy I am convinced.

Most morphinists desire to be free from their enslavement. They are universally condemned because of the belief that they are responsible for their vice and that by mere exertion of will power they could be free from it, and the medical profession rather joins in this lay view of the matter. But this view is based on ignorance, and it is as unjust as it is inaccurate. A morphinist successfully taken off of his drug and protected through the few weeks immediately following until his body and mind can be built up again will, in the vast majority of cases, stay off his drug, and the percentage of relapses among morphine patients is always smaller than among alcoholics. The alcoholic and the cocainist are prone to have a lurking desire to go back to the sensation of expansive personality, and go back to the time when they could believe that they possessed the power of accomplishing all that they hoped for and dreamed to do. But the morphinist looks with horror on the enslavement of his habit, and the majority dread to return to it.

Of recent years there has been a growing number of patients addicted to still another form of narcotic indulgence, that is, the addiction to the various forms of coal tar hypnotics. Formerly, some thirty years ago, one saw examples of the chloral habit, for chloral then was considered the ideal hypnotic and had proved its worth to cause sleep, but the profession realized that with the use

New York Medical Journal, Nov. 14, 1914.

of it there arose the possibility of a genuine habit. They thought then it was due to the drug itself, and failed to realize that the condition necessitating the giving of hypnotics was the fundamental cause of the formation of the habit. To evade, therefore, the possibility of a habit-forming drug, various new substances have been used hoping to obtain the hypnotic result without producing the habit-forming qualities.

The dreamless sleep of tired childhood stands in all our minds as the ideal rest that body and mind desire when night comes round after each day's work, but that ideal boon is not given to all wearied souls even in health, and when afflicted with mental worries or worn out with the strain of life or disturbed by physical disease, the restful, dreamless sleep does not come, and each succeeding day has to be taken up by tired humanity without the healthful rest and recuperation from the previous night's natural sleep. The habits of the human mind regarding sleep are as full of idiosyncrasies as the rest of human psychology. Human beings can sit up all night in the pursuit of pleasure, dance or read, or play bridge or poker, and be proud the next day that they can go about their work and show so little strain from that which gives them pleasure, but let these same individuals when they desire sleep toss and turn for a small part of the night, and fail to obtain the desired sleep, the next morning their mind and talk are full of woe and self pity for the terrible strain and wearisome night they have been through. They crave sympathy from each friend and desire condolences that they have not slept a wink. Many nervous people begin in the afternoon to fear that they will not sleep, and by night time they have a growing dread of the weary, racking hours of the night in which they must lie wakeful and restless until morning comes. They honestly endeavor to go to sleep, and lie there straining to sleep, and by such straining to sleep, and such fear that they will not sleep, do they drive away sleep hour after hour. Well did the ancients conceive that there was a god of sleep, for they must have realized that the more he was wooed the more did he flee from them, but when treated with indifference how quickly did he return and fall upon the indifferent mind. Few people indeed can bring themselves to such a philosophical view of sleep or the lack of sleep and can contemplate the wakeful night with indifference. Hence, with the increasing strain of existence and with the increased intensity of the wear and tear of life, humanity has demanded a hypnotic that sleep may be brought about when naturally one cannot obtain it.

The theoretically ideal hypnotic would be that amount of muscular fatigue products that would bring about the required effect. There is no question that physical exercise in the fresh air is the best hypnotic, but this is not always obtainable in our modern city life, and the profession has been vainly seeking some drug that will benumb the higher consciousness of the mind and leave no ill effects. Most of the drugs proposed have some bye effects that remain the next day in their mental heaviness, or drowsiness, or headache, or even some motor effect. Certain of the common hypnotics leave behind them a changed disposition. This is particularly true of the barbaturic acid group, usually sold under the names of veronal, medinal and luminal. The patients are out of sorts, there is a peevishness developed in the disposition, they are mean towards their companions, they like to say mean and cutting things, ill natured and viciously stinging, their minds are benumbed and they are not themselves; in some people this barbaturic acid group causes a very intense motor incoordination, so that even with 5 or 10 grains I have seen patients stagger as if drunk with alcohol. In larger doses of 20 or 30 grains I have seen patients unable to walk. When mixed with alcohol it seems to be particularly benumbing. This barbaturic acid group produces a genuine habit formation, and the patients quickly show a mild dementia, or in the chronic poisoning a very distinct and pronounced dementia. This group of hypnotics is one of the most widely used and usually considered one of the most harmless, but in my experience it is one of the most harmful, and produces the greatest functional changes in the mentality of its users.

The hypnotic habit is a widespread and increasing one, but one the consequences of which are too lightly considered by both the layman and the medical profession. Ill-natured peevishness brought about by these drugs can work an incalculable harm in the patients' daily life, and can go on increasingly and the real cause of their changed disposition can remain unrecognized unless the profession is awake to the symptoms caused by some of these hypnotics. I do not expect to revolutionize the habits of the laity or of the profession by any warnings, however timely, but I am sure that when the injurious mental bye effects of many of these drugs, especially the barbaturic acid group, is recognized, there will be less poisoning of humanity by these drugs and many an unhappy problem will receive its solution through the recognition of these facts. I have had under my care several patients suffering from the chronic poisoning by these hypnotics, and in treating them I have found the same impulse for narcotic intoxication driving them to this indulgence as I have found in other patients who have sought relief from opium and its alkaloids.

Does this conception of the intoxication impulse and the causation of alcoholic and other drug indulgences help us in the solution of these problems? It seems to me that it does. It forces us to the logical conclusion that in the mass of humanity which we meet in hospitals, this mass of humanity that we mistakenly punish to-day and turn from an occasional intoxication into chronic alcoholism, and with which we fill our police courts, our workhouses, and our alcoholic wards, that this same discouraged, hopelessly discarded mass must be regenerated through a change in their environment and through their work and recreation. It is among this mass that the missions and the Salvation Army, through their religious influences, have produced the greatest results, and they have done so because, when religious influence has changed a man's outlook and started regeneration, the man himself has also changed his environment and his companionship in that environment, and thus he has succeeded unconsciously in working out the problem of rehabilitation. We have heretofore taken the poisoned mind of the alcoholic and insisted that it should act in a normal manner, and have doled out punishment and condemnation when it has failed to act normally, instead of medically unpoisoning that mind and then building up the body and permitting the mind to build up with it as near normal as it was possible to arrive. As our medical knowledge has developed we have realized that disease is a perversion of the normal functions in the body, and

yet we have failed to act with the alcoholic on this realization, for the poisonings by alcohol or by drugs produce certain perversions of normal functions and these intoxications as truly represent a form of disease that requires medical treatment as any of the infections which we so classify as a matter of course. Alcohol differs from opium in the effects produced in the body. Alcohol destroys the essential cells of the viscera, degenerates the blood vessels, and increases the connective tissue growth. These three processes, varying in degree in any given individual, produce innumerable variations in the amount of degenerations and destruction. Alongside of the destruction there is always some degree of functional poisoning from which the cells can recover if the poison be eliminated and cease to act. Thus, until an alcoholic is unpoisoned and built up, one cannot say how much of the poisoned and degenerated personality it is possible to redevelop. Opium and its alkaloids and the coal tar products, on the other hand, poison only functionally; they do not produce tissue changes. Hence the elimination and cessation of action of these poisons permit a full recovery, even though most patients build up more slowly from the opium than from the alcoholic poisoning.

The problems then as they occur to us can be summed up as those of a physically poisoned body and mind that must be medicinally dealt with and physically unpoisoned. When this shall have been accomplished there remain the problems of psychology, and we are dealing in the vast majority of cases with psychopathology; we are dealing with the sick-souled, misunderstood personalities, distorted from many causes. We must learn to recognize the abnormal psychology of each individual and deal with that individual in whatever way the situation leads. It is often an economic situation that has to be readjusted; it is almost always a psychological distortion that has to be straightened out, and it is usually a social readjustment that has to take place. But with infinite patience and infinite persistence we can deal with and solve the problems presented by the distorted psychology of this unhappy group of patients.

WHAT FIRST AID IN RAILWAY SURGERY DOES NOT MEAN; AND WHAT IT ACTUALLY DOES MEAN.*

By DONALD McCASKEY, M.D.,

WITMER, LANCASTER COUNTY, PA.

There is a fallacious notion that the moment a man is injured he must be rushed at breakneck speed to the nearest hospital. To get there quickly and at all costs is the idea. Everybody tries to help achieve this purpose. It does not matter much whether the injured one is suffering from a hemorrhage; whether he has been profoundly shocked; whether an agony of pain exists—haste is the dominant thought. Every process is speeded up to achieve this end. But this is wrong. It is an extravagant waste of the vitality of the injured patient to be rushed under all conditions to the nearest hospital.

First aid does not mean that our machinery must be set in motion with the same dramatic fervor as do we see our city fire department respond to the alarm of fire. Neither does first aid mean the theatrical and skilled ability to put a bandage around a man's injured head or injured arm or leg in the seventeenth fraction of a second such as we see in motion pictures, particularly. This all looks very wonderful and awe inspiring to the average spectator—of whom there are usually many standing around loudly criticizing what should not be done and very emphatic in the declaration as to what you should do.

The major thing to decide in all our first aid work is "What is the best for the injured man or woman"? Certainly haste is not the chief requisite.

Here is another point. Oftentimes when a person is injured it is absolutely wrong for that person to be lifted by unskilled hands. The tender sympathies of the surrounding bystanders may be strongly aroused and every effort may be made by them to afford the injured one such degree of first aid care as they may be able to administer. However, first aid does not mean this type of help, for it is simply and solely because the average type of first aid help is so unskilled, imperfectly trained and utterly incompetent,—oftentimes not trained at all in the modern methods of first aid science,—that bad results accrue.

We don't want to sacrifice everything to speed in our first aid work. Thorough training and first aid competency is the great essential in all our efforts which we should get in behind and work for.

What first aid actually does mean is that kind of aid given to an injured man by a thoroughly competent trained helpmate who has made a special study of first aid principles and practices, proving himself to be a first aid expert possessing a comprehensive practical knowledge rather than but a half and utterly inadequate training about the treatment of wounds, bruises, fractures, sudden illness, etc., etc.

Please get these two facts clearly fixed in your mind: (1) A wound although superficial is often treated by anyone wherever there is a handy first aid package (and these are scattered everywhere). This wound might lead to an infection, simply on account of an unclean condition of the person applying the dressing from the first aid package. Such an infection, because of incompetent first aid treatment would, therefore, cause the injured man to lose time, which time loss is not only a loss and a waste to the man, but also to the company employing him. (2) By having a thoroughly trained man where a superficial wound can be treated in a proper aseptic manner the injured man, in a great many more instances, is able to continue with his work and have his wound redressed as the occasion requires. This method does not cause any undue waste of time; likewise the company does not lose his services on account of his wound becoming infected from improper first aid treatment in the beginning.

There are new standards of efficiency which have developed in medicine and in surgery and in first aid to the injured during the past decade, just as there have been improved standards developed in the operating department of the Pennsylvania Railroad. New principles have been searched for and developed as the need would arise for more adequate measures of workmanship. Instead of the old principle of speeding an injured man to the hospital with all dispatch, irrespective of his physical condition, I respectfully refer to the newer

*Being part of a discussion before the second annual Industrial Welfare and Efficiency Conference of the Pennsylvania Department of Labor and Industry, Harrisburg, Pa., November 17, 18, and 19, 1914.

principle evolved of *taking the hospital to the injured patient*, as is now employed on our Philadelphia Division of the P.R.R. in the Enola Shop and Freight Yards. At these yards, where over a thousand workmen are employed, General Foreman C. D. Gray has made over an old wrecking train car into a hospital car. He placed one of his men in charge of this car thoroughly stocked with sterilizers, surgical solutions, bandages, dispensing tablets, stretchers, blankets, etc., etc. Everything complete and in readiness to take the hospital to the injured man as soon as the engine can be coupled to this car.

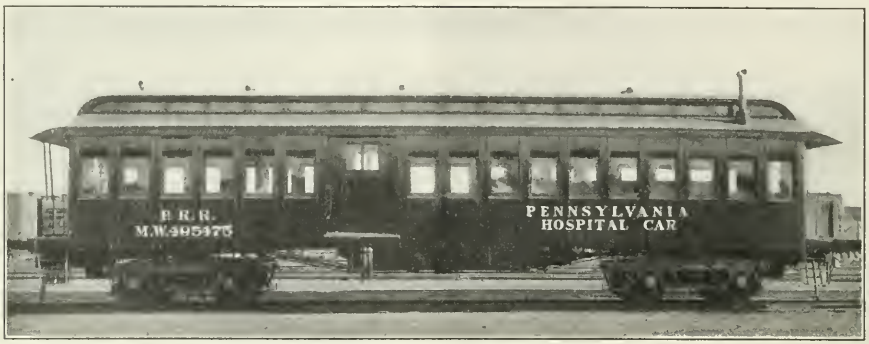

FIG. 1.—The hospital car at the Enola shops, P. R. R.

The following is a list of supplies on the hospital car:

Cupboard (A)—6 wool blankets, 3 rubber blankets.

Cupboard (B)—4 meat platters, 4 sugar bowls, 1 coffee pot, 1 frying pan.

Cupboard (C)—6 wool blankets, 3 rubber blankets.

Cupboard (D)—2 dippers, 3 meat forks, 3 large spoons, 26 knives, 31 forks, 23 table spoons, 34 tea spoons, 1 can opener, 1 steel, 1 butcher knife, 28 soup bowls, 1 4-qt. pitcher, 1 1-qt. pitcher, 1 2-qt. pitcher, 5 cups, 5 salt shakers, 4 pepper shakers, 6 tin cups, 1 frying pan, 1 roaster, 28 dinner plates, 1 stewing pan, 3 basins.

Cupboard (E)—1 bottle iodine, 24 first aid boxes, 4 1-lb. boxes absorbent cotton, 6 5-yds. packages of Red Cross gauze, 1 pound bottle of antiseptic discs, 1 pint bottle of alcohol, 1 roll adhesive plaster 12 in. wide 5 yds. long, 12 roll 3-in. Linton gauze bandage, 28 rolls 2-in. Linton gauze bandage, 40 rolls 1-in Linton gauze bandage, 32 different sized splints.

Cupboard (F)—1 5-gal. can, 1 coffee pot, 1 bag ground flax seed, 1 can litholine, 2 Schapps tourniquets 36 in., 2 Esmarch tourniquets, 1 Fowler's infusion apparatus.

Cupboard (G)—2 rolls antiseptic towels, 2 boxes individual drinking cups, 4 cotton blankets.

Cupboard (H)—4 rolls 3-in. gauze bandage, 5 rolls 2-in. gauze bandage, 4 rolls 1-in. gauze bandage, 6 hot water bottles, 1 ½-lb. bottle chloroform, 100 tablets physiological salt solution, 1 drop bottle for chloroform, 1 pilling folding Yankauer mask, 1 bottle Martin's toilet wash, 4 bottles Carron oil, 1 bottle antiseptic discs, 1 bottle compressed boric tablets, 1 bottle spirits of ammonia, 1 bottle cocaine, 1 jar moist gauze 5-yds., 3 medicine droppers, 1 eye cup, 5 1-yd. packages gauze, 10 1-oz. packages absorbent cotton, 1 box Thymol iodide, 1 bottle chlorodyne, 1 aseptic hypo syringe, 25 hypo tablets atropine sulphate 1-100 G, 25 hypo tablets morphine sulphate 1-4 G, 25 hypo tablets strychnine sulphate 1-30 G, 25 hypo tablets digitalin pure (German) 1-50 G, 1 1-lb. bottle of Dioxogen.

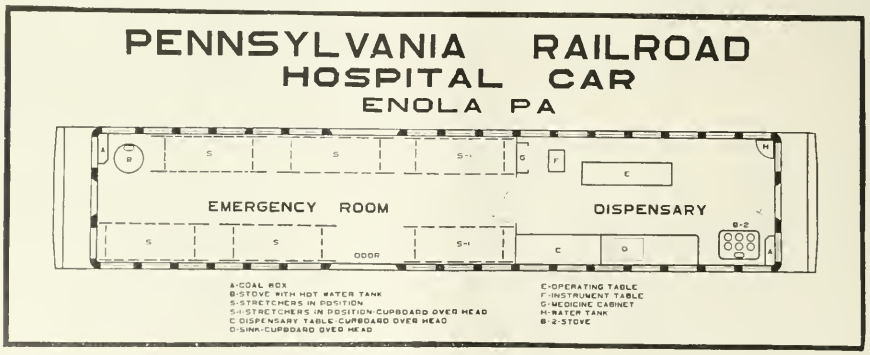

FIG. 2.—Floor plan of the hospital car.

Drawer (J)—12 towels.

Drawer (K)—5 pillows, 12 pillow cases, 11 sheets.

Miscellaneous—8 stretchers, 1 operating table, 1 slop bucket, 4 cots and mattresses, 3 tables, 6 benches, 8 chairs, 6 camp stools, 1 instrument table.

When a workman is seriously injured now, instead of the injured man being lifted and bumped and oftentimes being made to lose a quantity of blood in addition to suffering a greater amount of shock, the hospital car is pulled up to the injured man. Under the competently trained direction of the Red Cross attendant the injured man is promptly treated by the standards of first aid. For instance, if he suffers from badly lacerated muscle wounds of the thigh, a solution of tincture of iodine is poured directly into the wound. Then it is carefully dressed with sterile bandages and the man passed on to the hospital, still in the same car and under the same skilled care of the attendant who never touches a wound or makes a dressing without first of all having thoroughly scrubbed his hands. There is little suffering to the injured man, little loss of blood and little of the unavoidable shock. The injured man's chances by this new principle of taking the hospital to the man are immeasurably increased for a prompt recovery and a much sooner return to duty than when he is handled by the average half-trained first aid spectator or employee. Merely to apply mechanically a lot of bandages, no matter how cleverly the series of movements may be carried out is not modern efficient first aid.

Here is a point we all need to realize.

Oftentimes a man who is not very much injured is induced to believe that he is seriously hurt if suffcient dramatic first aid efforts are employed by the bystanders attempting to render the best aid they know how to render when their hearts' sympathies are stirred. I have a further theory that many an injured man or woman whose injury is slight is oftentimes started on the road to malingering, just because of incompetent applied first aid treatment at the initial stage of the accident. Whenever possible, therefore, the most efficient type of first aid is to take the hospital to the injured man. In large industrial concerns, first aid hospital trucks might be effectively utilized in place of hospital cars.

We do not need to obtain an exaggerated idea of the importance of first aid in its actual meaning as a contributory measure towards better efficiency. We should merely try to keep ourselves up to the best standard, and one of these I respectfully repeat

Fig. 3.—Interior of the hospital car showing two cots ready for use. Along the side of the car are many stretchers, each equipped with blankets. Boiling water is kept constantly on hand in the tank at the end of the car.

again is the first aid hospital car in railroad accident work as already in use on the P. R. R.

Cases Given First Aid Treatment in Enola Hospital Car

	Burns	Injuries to Head	Injuries to Eye	Other Injuries	Injuries Re-dressed	Hospital	Total
June	2	25	35	90	120	1	273
July	0	7	33	45	50	1	136
August	0	12	31	55	41	0	139
September	2	14	22	55	42	1	136
October	3	14	30	42	49	3	141
Total	7	72	151	287	302	6	825

First aid should be regarded on the same plane of efficiency much as was the problem of the P. R. R. wrecked bridge at Tyndall, Ohio, just east of Co-

lumbus. This bridge was a four-tracked structure six hundred and fourteen feet long, weighing two and a half million pounds, and was washed from its bearings by the 1913 flood. It had been planned according to the best available standards of information over a decade ago. But, and here is the point—after the 1913 flood of the Muskingum River when the river bed was gouged out and washed away to much deeper channels, and the masonry work and abutments were destroyed, and general havoc played, the engineering department of the P. R. R. found it necessary to reconstruct their bridge building to meet the stiffest, biggest flood of the future which might sweep down the Muskingum River. The engineering department, therefore, improved their efficiency standards. They constructed a seven hundred and twenty foot bridge in length. Instead of two and a half million, they built it seven million pounds, thus providing extra strength to meet the growth of traffic and possible worse floods of the future. It is along much the same lines that our application of first aid principles must be made. Half knowledge regarding first aid means a loss, not only to the injured employee, but to the employer. When we expect men to apply this half knowledge in treating an injured individual it is about as wasteful as would be a group of engineers who would attempt to construct a railroad bridge like the one at Tyndall, Ohio, with only half knowledge of the actual conditions they were going up against.

It is exact, it is thorough knowledge efficiently applied that we need in our first aid work of the future. One man thoroughly trained in first aid work in every railroad crew is worth much more than any number of men only half trained.

First aid has certainly outgrown its swaddling clothes. We must recast our ideas and our methods of coping with the injuries of the future. When we can save an injured person the loss of vitality by the avoidance of unnecessary nerve shock from ignorance in sympathetic handling and lifting; when you,—and I say you advisedly, because possibly at some future time you may be called upon,—when you can treat an injury so as to avoid any possible germ contamination from meddlesome technique because of inadequate and incompetent training, you are giving the injured man or woman the best possible degree of first aid treatment, and only then. A first aid package of gauze and iodine solution is not enough. It requires the man behind the gun and not a horde of half trained men standing with a first aid package in their hands, who may possess the tenderest of sympathy for their injured comrade and fellow workman, but who lack the competency and safety-first thoroughness that goes with special first-aid study and training, embodied in the newer principle of Competency.

Fig. 4.—Operating room in the hospital car; there are sockets in the car deck in which the feet of the operating table are sunk. In the lockers on the left side above are blankets, surgical dressings, bandages, etc.

Heterogenetic Sera.—F. Micheli and F. Negro point out that this term is used in contradistinction to the expression immune or isogenetic sera and is based upon the fundamental investigations of Forssman who in 1911 demonstrated that the guinea-pig responds to the parenteral introduction of a fine emulsion of various organs of the rabbit with an active production of hemolytic amboceptors for the red blood cells of the sheep.—*Archivio per le Scienze Mediche.*

AN EXPERIMENTAL STUDY OF A NEW REMEDIAL AGENT AND OF ITS EFFECTS IN PULMONARY TUBERCULOSIS.

By BERTRAM H. WATERS, M.A., M.D.,

NEW YORK.

SENIOR INSTRUCTOR IN PHTHISIOTHERAPY AT THE N. Y. POST GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN TO RIVERSIDE HOSPITAL-SANATORIUM; CHIEF OF TUBERCULOSIS CLINICS, THE DEPARTMENT OF HEALTH.

THE employment of inhalations, in the treatment of pathological conditions of the respiratory tract, has appealed to many as a rational therapeutic procedure, and medical literature is replete with descriptions of generators, vaporizers, and pneumatic cabinets, together with the various substances thought to possess remedial properties, which have been employed. A review of this literature is interesting, showing that from the earliest times the subject of inhalation has held an important place. As early as 1664 this method was applied by Bennett in the treatment of pulmonary tuberculosis. Laennec in 1810 employed it with considerable success; Schneider and Valz constructed the first nebulizer in 1829, and Auphan applied pulverization and nebulization in the treatment of chronic diseases of the respiratory tract in 1847. About the same year Salles-Girons established an inhalatorium at Pierrefonds, and for the first time the question was raised of the possibility of reaching the lungs by these methods. A lively discussion followed, and repeated experiments by such investigators as Dumarquay, Fournie, Bourouilloux, Gratiolet and Travenier, Poggiale, Gerhardt, Waldenburg, and Solis-Cohen, have finally demonstrated that by pulverization and nebulization remedies may be efficiently administered, the latter observer even going so far as to state that a physician had not done his full duty, in some cases, unless he resorted to such methods. Many other studies of this subject have been made, among the more recent being those of Heryng (1902), Freund (1907), Foxwell (1907), Cointet (1909), and Bulling (1909), the general result of which has been one of approval. Though the therapeutic and even the germicidal action of inhaled sprays, especially, has been confirmed, such action seems to be limited to the surface of the respiratory mucous membrane, and the influence upon pathogenic conditions, such as tubercle, in the lung tissue, is very problematic.

The ethereal oils and the balsams have been found to be the most useful substances for inhalation, oil of turpentine, oil of eucalyptus, oil of cade, the balsams of peru and tolu, and creosote, having been employed with more or less success, either in vapor form or nebulized by means of atomizers and nebulizers.

Oil of turpentine and some of the other volatile oils, owe their therapeutic value to terpenes. The terpenes are hydrocarbons having the composition represented by $C_{10}H_{16}$, or some multiple of that formula. The principle common to all terpenes is *pinene*. It is a constituent of the volatile oils of the pine family and of several other families of plants. This study deals not with turpentine, the complex oleoresin of the pine tree, but with its chief constituent, pinene. To it are attributed the physiologic and therapeutic actions of oil of turpentine.

Locally, pinene is a powerful stimulant to the skin and mucous membranes. It is also antiseptic and bactericidal, and appears to be especially antagonistic to the typhoid bacillus. When taken by a healthy person, in moderate doses, it produces a sense of warmth in the stomach, soon followed by exhilaration, and, if the amount be sufficient, giddiness and even a species of intoxication. The pulse is increased in force and frequency. Pinene is excreted through the lungs and kidneys, and its irritant action upon the latter and upon the genito-urinary tract is very decided.

Oil of turpentine, on account of the pinene it contains, has acquired a reputation as a hemostatic in passive hemorrhage from the stomach, intestine, lung, and uterus. It is often very efficient in ulceration of the bowels when taken by the stomach, probably acting locally in the intestine, and in old gastric ulcers good results are sometimes derived from its use. It is given internally as a diffusible stimulant of especial value in exhausting fevers. It has long enjoyed high repute as a remedy for the treatment of typhoid fever, especially if diarrhea persists and relapses occur, indicating unhealed ul-

A B

FIG. 1.—*Micrococcus pyogenes aureus*; A, control plate; B, exposed plate

ceration of Pyer's patches. Locally it is very useful as a counterirritant in pleurisy and bronchitis, applied in the form of turpentine stupes. Probably some of the benefits derived from turpentine stupes in pneumonia is due to inhalation of its vapor.

Standing in the way of a more general use of oil of turpentine as a remedial agent is its irritant action upon the kidneys and urinary tract. When its vapor is inhaled it is readily absorbed, and instances are recorded in which persons engaged in the turpentine industries have experienced renal inflammation.

When the vapor of pinene is exposed to a current of ozonized air, prepared by the action upon dry air of a high tension electrical discharge, an addition occurs between the pinene and oxygen, resulting in the production of a dense white vapor. To this substance I have given the name oxypinene, a convenient general term, descriptive of all combinations of pinene with oxygen, either as O_2 or O_3. It is, however, chemically a pinene monozonide, occurs also as a diozonide and other multiples of the oxygen atom, and readily dissociates into its active principles, peroxide of hydrogen and pinonic acid, aldehyde and ketone.

It possesses the valuable therapeutic properties of pinene without its irritating effects upon the kidneys and urinary tract. Applied to the skin and mucous membranes it acts as a mild stimulant, markedly differing in this respect from the powerfully irritating oil of turpentine. The vapor is respirable for hours at a time, and its use may be continued indefinitely day after day without producing symptoms of renal irritation. It is antiseptic and bactericidal when applied to cutaneous and mucous surfaces.

Antiseptic and Germicidal Properties of Oxypinene.—From pure broth cultures of typhoid, diphtheria, and colon bacilli, and staphylococcus, smears were made on cover slips. These were thoroughly dried in the incubator, and placed under a bell jar, into which oxypinene was allowed to enter through an opening near its base, and escape through an opening at the top which was lightly plugged with cotton. At intervals of forty minutes, one hour, one and a half hours, and two hours, a smear of each culture was removed and dropped into broth tubes. After incubation all the controls except that of diphtheria, showed growth. All exposed smears produced growth, except those of diphtheria.

The same organisms were used, but instead of incubator dried smears, large drops of broth cultures of each on cover slips, were exposed, in the same manner as previously, for fifty minutes, seventy minutes, and one hour and fifty minutes. After incubation, all controls showed marked growth. All exposed drops failed to produce growth, except that of staphylococcus, growth of which was markedly retarded and very slight. As all the exposed drops became dry before the expiration of forty minutes, and as in the previous experiment, none of the incubator dried smears were killed, it was concluded, either, that the organisms in all exposed drops were killed under forty minutes, or that at least some moisture is necessary to obtain a germicidal effect. As on theoretical grounds, the latter supposition seemed probable, the use of incubator dried preparations was abandoned.

Agar-agar, in petri plates, was substituted for cover slips, and upon the surfaces of these, broth cultures of the organisms already used were planted in streaks. These plates were then exposed in the manner already described, for one and one-half hours. All controls showed marked growth after twenty-four hours' incubation. All exposed plates produced no growth after five days' incubation.

A B

FIG. 2.—*Bacillus anthracis*: A, control plate. B, exposed plate.

Large drops of broth culture of the typhoid bacillus, after exposure on cover slips in the manner described, for twenty-five and forty minutes, were smeared upon agar-agar slant tubes. The controls showed marked growth after eighteen hours' incubation. The tubes inoculated with culture which had been exposed for twenty-five minutes, showed marked growth after twenty-four hours' incubation. The tubes inoculated with culture which had been exposed for forty minutes, showed no growth after ninety-six hours' incubation.

Large drops of broth culture of each of the organisms previously used were exposed in the same manner and for the same periods, as in the preceding experiment, and planted on agar-agar slant tubes. The controls showed marked growth after eighteen hours' incubation. The tubes inoculated

with culture which had been exposed for twenty-five minutes, showed growth after twenty-four hours' incubation. The tubes inoculated with culture which had been exposed for forty minutes, showed no growth after ninety-six hours' incubation.

The conclusion seemed to be justified that for typhoid, diphtheria, and colon bacilli, and the staphylococcus, in pure broth culture, when even the slightest moisture is present, oxypinene is germicidal in from twenty-five to forty minutes.

Upon the surface of agar-agar, in petri plates, broth culture of subtilis, anthrax, and pneumococcus were planted in streaks. These plates were exposed, in the manner already described for one and one-half hours. The controls showed marked growth after eighteen hours' incubation. The exposed plates showed no growth after forty-eight hours' incubation. At the end of five days no growth had appeared.

Upon the surface of agar-agar, in petri plates, broth cultures of typhoid, diphtheria, and anthrax bacilli, and staphyloccus were planted in streaks. These plates were exposed for two and one-half hours, not under the bell-jar, *but in a room* having a cubic capacity of about 2,500 feet. The room was fairly well filled with oxypinene. The controls showed marked growth after eighteen hours' incubation. The exposed plates, after twenty-four hours' incubation, showed no growth, except that of staphylococcus, on which a very slight growth appeared. After forty-eight hours' incubation, anthrax seemed to show slight growth, but at the end of seventy-two hours it had not spread, and a smear of it planted on an agar slant tube failed to produce growth. A single agar petri plate, on the surface of which the same organisms, in broth culture, had been streaked, was exposed under the bell-jar, for two hours, and failed to show growth of any organism, after seventy-two hours' incubation, while anthrax overgrew all other growths, on the control plate, after twenty-eight hours' incubation.

These experiments have been repeated many times, in the same manner, with uniform results, and from them it seems conclusive that oxypinene is a germicidal gas, of high efficiency, which is at once respirable and easily produced, continously, in large quantities.

Figures 1 and 2 are photographs from agar-agar petri plates upon which were planted pure cultures of *M. pyogenes aureus*, and *B. anthracis*. Similar experiments with similar results were made with cultures of *B. typhosus*, *B. coli communis*, and *B. subtilis*, but lack of space has necessitated our omission of illustrations of the same. These plates were exposed to the action of oxypinene for two and one-half hours, in a room of about 2,500 cubic feet capacity, in which the generator was constantly operating and keeping it fairly well filled. Control plates were made of each organism, and both exposed and control plates were incubated for seventy-two hours.

Clinical.—Observations were made of twenty-one patients. As with two exceptions they were of the dispensary class, they were difficult to control for as long a period as could be desired, some insisting upon their discharge with the alleviation or disappearance of their active symptoms. With the exception of Case V, a very early tuberculous infection, and Case 21, a child ill with pertussis, following an unresolved bronchopneumonia, all were in the second or third stage of pulmonary tuberculosis

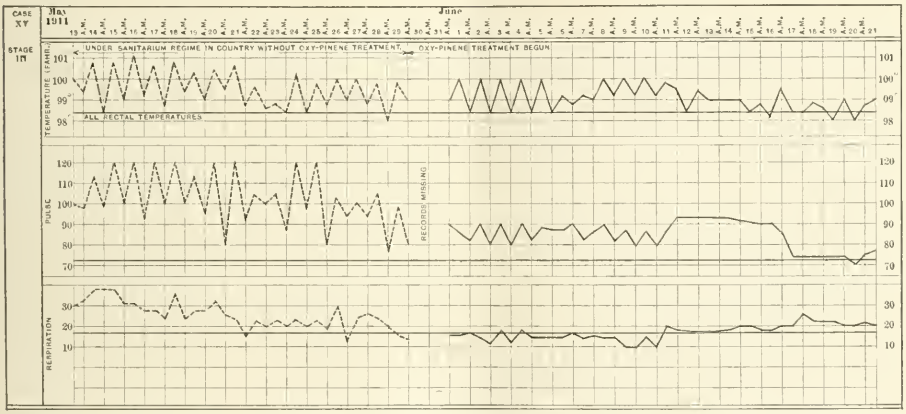

Chart 1.

(Classification of the National Association for the Study and Prevention in Tuberculosis), and tubercle bacilli were demonstrated in the sputum. It seemed desirable to select lesions of such severity, but equally so that they should offer some hope of improvement, in order that, as far as possible, the amelioration of symptoms which so often follows any change in environment, and dietic regime, might de discounted. However, to study fully the effects of oxypinene upon special symptomatic features or types of disease, such as active hemorrhage, marked pyrexia, constant dyspnea, tuberculous laryngitis, acute phthisis, chronic pulmonary tuberculosis, and the toxemia of extensive cavitation with secondary infection, certain patients were admitted to treatment whose prognosis seemed hopeless, and who, though showing for a time the beneficial effects so generally observed in the others, finally died. With the exception of Cases XX and XXI, who were treated in their own homes, the entire group was observed in a private hospital in the city, for three months and thereafter for five and one-half months in a private sanatorium in the country. The periods of observation varied from nine days to nine

months. With a few exceptions all were studied according to the following routine. Each was observed in bed, for forty-eight hours before beginning treatment, during which time two hourly records of temperature (rectal), pulse, and respiration were made, twenty-four hour total amounts of urine and sputum examined, and a hemoglobin estimation and differential blood count made, in addition to a complete physical examination. Thereafter temperature (rectal), pulse, and respiration were recorded every twenty-four hours or twice daily, weights were taken, twenty-four hour total amounts of urine and sputum examined, and a hemoglobin estimation and differential blood count made, weekly. Twenty-four total records were also kept of urine and sputum daily. Physical examinations were made at

In no other respects were the routine and conditions of observation varied. During the first epoch treatment was given continuously, with only sufficient open air for proper ventilation, and several of the patients had no direct sunlight, their windows opening on a court. During the second and third epochs, treatment, when given at all, was continuous during the night, and for periods of from one to two hours twice during the day, the remainder of the time being spent in the open air. The blood, sputum, and urine examinations were made by the Lederle Laboratories, the Higgins Laboratories, and by my assistant and resident, Dr. W. A. Glanville. While there is probably some variation of results because of differing personal equation, they have been so checked up as to make this negligible, and in Cases

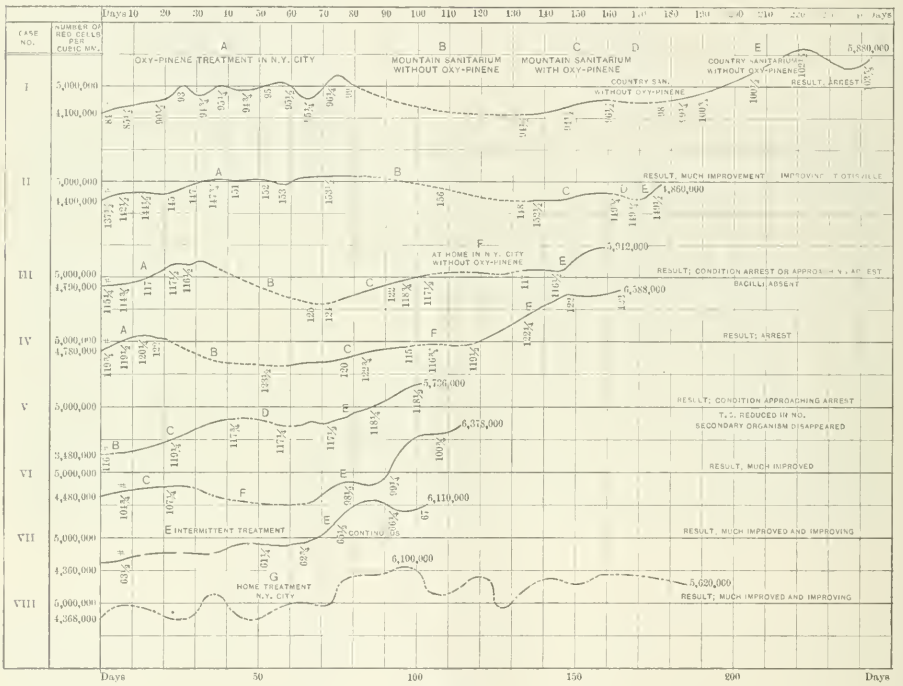

CHART 2.

frequent intervals, and at least once a month. The patients were in bed or up and about, as their temperatures or general condition required, and no other treatment was given, except cathartics, and heroin or codeine occasionally. In some instances an iron preparation was used to study the behavior of the hemoglobin. The diet consisted of three wholesome meals daily, and one raw egg in one glass of milk twice daily. Partly through circumstance, partly with the design of checking up and controlling results, the period of observation was divided into three epochs. The 1st, for three months, in the city; the 2nd, for two and one-half months in a sanatorium in New York, at an elevation of 1,500 feet; and the 3d, for three months in a sanatorium in New Jersey, at slight (500 feet) elevation. During these epochs an opportunity was afforded of observing and contrasting the effects of ideal sanatorium régime without, and also with, oxypinene treatment.

XX and XXI all these examinations have been made by the same examiner.

The following indicates the types of cases studied:

	Stage I	Stage II	Stage III
Number of cases.	1 (Case V)	4 (Cases XIII, XIV, XVI, XVII)	15 (all other cases)

The other case, XXI, was the child referred to with pertussis, following an unresolved, possibly tuberculous, bronchopneumonia.

As space is lacking for a detailed description of each of these, a brief synopsis of several, together with the blood findings, and the temperature curves of two, are given. These are average cases, and illustrate the points noted.

CASE I. *Woman, 34 years, Stage III, Improved.* General condition poor. Extensive infiltration, both upper lobes with softening, especially on left side, where there is well marked cavitation. Complicating nephritis. Moderately toxic. Sputum positive.

Red Cells	Hb.	White Cells	Weight	
3,750,000	75	8,200	96	Before treatment.
4,960,000	81	13,600	101½	After one month's treatment

Constant racking cough, with thick tenacious sputum. Sputum increased from 15 c.c. to about 150 c.c. daily with relief of cough. Discontinued treatment against advice, because of being needed at home, and her condition becoming again progressive, she died eight months later.

Case VI. *Woman, 24 years, Stage III, Arrested.* General condition poor. Fairly diffuse infiltration, right lung with softening in upper lobe anteriorly. Thickened pleura with adhesions, lower portion. Infiltration left apex. Little toxemia. Sputum positive.

Red Cells	Hb.	White Cells	Weight	
4,100,000	75	10,000	84	Before treatment.
5,100,000	92	13,300	99	After six weeks' treatment.
5,552,000	78	15,060	103½	After 7½ months' treatment.

These cases illustrate the effect upon the sputum, with relief of cough, the changes in the blood picture, and what is usually observed, and is an indication of such result, a white cell count, which remains high in favorable and arrested cases. In several instances, though not uniformly, the hemoglobin percentage has fallen after ceasing treatment.

Case VII. *Woman, 24 years, Stage III, Improved.* General condition fair. Infitration right upper lobe without softening. Diffuse infiltration left upper lobe with cavitation. Complicating emphysema and general bronchitis. Little toxemia. Sputum positive.

Red Cells	Hb.	White Cells	Weight	
4,400,000	86	7,200	137½	Before treatment.
5,170,000	92	12,100	153½	After 2½ months' treatment.
4,860,000	82	12,800	149½	After 5½ months' treatment.

During the last three months, treatment which had been continuous was interrupted, but patient was under sanatorium régime, in the country. She was then admitted to a sanatorium, where previously she had been refused admission on account of the extent of her lesion.

Case XII. *Man, 41 years, Stage III, Improved, Approaching arrest.* General condition fair. Infiltration both upper lobes, with areas of softening and fibrosis; small cavity in right upper; left lung adherent at base; left chest much contracted. Complicating chronic bronchitis of years' duration. Little toxemia. Sputum positive.

Red Cells	Hb.	White Cells	Weight	
4,790,000	81	11,600	115½	Before treatmeot.
5,942,000	91	10,420	116½	After 5 months' treatment.

Tubercle bacilli disappeared from the slight morning sputum, and he returned to employment.

Case XIII. *Man, 28 years, Stage II, Arrested.* General condition fair. Extensive infiltration right upper and middle lobes, with softening in the upper. Infiltration left apex. Moderate toxemia. Sputum positive.

Red Cells	Hb.	White Cells	Weight	
4,780,000	81	9,200	119½	Before treatment.
6,588,000	85	13,200	122	After 6 months' treatment.

Returned to employment.

Case XV. *Man, 21 years, Stage III, Improved, Approaching arrest.* General condition poor. Infiltration right upper lobe, and scattered areas throughout left lung, with softening in upper lobe. Considerable toxemia. Sputum positive.

Red Cells	Hb.	White Cells	Weight	
3,480,000	66	22,400	116	Before treatment.
5,736,000	73	12,400	118½	After 3½ months' treatment.

As he felt well he refused longer to continue treatment and returned home. Lesion still active. Tubercle bacilli were reduced in number and all secondary organisms had disappeared.

Case XVI. *Man, 28 years, Stage II, Arrested.* General condition poor. Diffuse infiltration right upper lobe, with softening. Scattered infiltration throughout rest of lung. Infiltration left apex. Considerable toxemia. Sputum positive.

Red Cells	Hb.	White Cells	Weight	
3,110,000	66	7,600	109	Before treatment.
5,530,000	96	12,220	110	After 2½ months' treatment
6,422,000	104	14,210	115½	After 3½ months' treatment

Interesting in that for two and one-half months he received no inhalations, but was under sanatorium régime in the country. Inhalations were begun there, and after two months he returned to employment. Slight morning cough persisted with about 5 c.c. of sputum daily, from which tubercle bacilli and all secondary organisms had disappeared.

Case XXI. *Child, 2½ years.* Pneumonia two months previously, coughing continuing with failing health. Apparently had pertussis. General condition extremely poor; pale, languid and apathetic. Respiration 60, pulse uncountable, a feeble cough with each expiration. Both lungs full of moist rales. Over right lower lobe voice intensified and respiration bronchovesicular.

Red Cells	Hb.	White Cells	Polys.	Lymphs.	
5,536,000	62	84,000	62 8	34 6	Before treatment.
5,460,000	70	27,000	34 0	53 6	After nine days' treatment.
5,480,000	79	39,000	41 0	54 4	After sixteen days' treatment.

Apparently made perfect recovery. Reported well since.

Case XX. *Man, 41 years, Stage III, Improved.* General condition fair for duration of disease (8 yrs.) Nutrition had been well maintained. Infiltration right upper lobe. Extensive diffuse infiltration entire left lung, with large cavities in both lobes.

Red Cells	Hb.	White Cells	Average Daily Urine, c. c.	Per Cent Urea, Gm.	Weekly Sputum, Oz.	Hours Treatment Monthly,
4,368,000	74	24,100	350	10.5	90	Before
4,480,000	80	30,500	425	32 4	142	174
4,960,000	86	14,400	980	19 4	92½	152½
5,984,000	84	19,200	1,023	14.2	85	144½
4,860,000	78	22,000	773	17.6	87	121
5,920,000	76	16,400	807	29 2	90	88½
5,620,000	73	17,400	883	25 4	87	67½
6,208,000	72	23,200		18 2	87	
5,800,000	75	20,000		17 4		

After completing a second sanatorium course returned home and for fourteen months previous to treatment had been confined to bed. During treatment toxemia was reduced (see temperature and pulse curve, Chart I) there were no hyperidroses, and after the fourth month, no rigors. He was able to be dressed, and about his rooms, and to do something for himself. The enormous cavities continued large daily secretions and were a constant source of exhaustion. A permanently favorable result could scarcely be expected. Tubercle bacilli greatly diminished in number, and all secondary forms disappeared. Improvement continued and he was able to return to business for part of the day.

The results of treatment may be indicated as follows:

	Stage I	Stage II	Stage III
Unimproved			1 (Case III)
Improved	1 (Case V)	2 (Cases XVI, XVII)	9 (Cases I, VII, VIII, IX, XII, XV XVIII, XIX, XX
Arrested		2 (Cases XIII, XVI)	1 (Case VI
Died			4 (Cases II, IV, X, XI)

Case XXI was markedly improved.

This classification is conservative, as of the Stage II cases, one, Case XVII, reported as improved, was in a condition approaching arrest, but would not remain longer under observation, and of the Stage III cases, three, Cases XII, XV, and XIX, reported as improved, were also in a condition approaching arrest, and two of them have returned to employment.

Accurate studies of the blood of tuberculous patients are of comparatively recent date. While many observations are recorded in the literature, they are confused by a lack of agreement among the reporters, either in their technique, or in their identification and classification of the several cellular constituents of the blood, or in their interpretation of the frequent and often rapid variations noted in

their numbers and forms. Even to-day, with our fuller knowledge of hematology, the personal equation of the examiner influences considerably a differential count, and there is more or less difference of opinion among hematologists as to the meaning of certain findings. What are probably the first entirely reliable studies were made by Ullom and Craig. From observation of thirty-nine patients reported in 1906, they conclude:

1. In pulmonary tuberculosis, without cavity formation, a mild anemia, with a decrease in erythrocytes and a relatively greater decrease in hemoglobin is constant.

2. From the standpoint of prognosis, an increase of the erythrocytes, in cases without cavity formation, is of favorable significance.

3. In advanced cases a decrease of the leucocytes is of unfavorable import.

4. In our investigations we have received the impression that the actual increase of lymphocytes seems to correspond to the increase of resistance on the part of the organism to the tuberculous infection, but further study is required to confirm this deduction.

5. The transitionals seem to follow the same rule as the lymphocytes in this regard.

6. At the beginning of the investigation the cosinophiles seemed to increase with the patient's improvement, but further study did not support this view.

Curry, in studying the effect of altitude upon the blood, found in normal and tuberculous individuals, an increase in red and white corpuscles, but notes little variation in the different kinds of leucocytes, while Webb and Williams have shown an increase in the proportion of the mononuclear cells, in normal persons, and in cured, stationary, and improving tuberculosis. That under various forms of treatment the blood findings correspond closely with those of Ullom and Craig, has been shown by Solis-Cohen and Strickler, who from 182 blood counts of fifty tuberculous patients treated with Bier's hyperemia, blisters, iodoform, creosote carbonate, and nuclein, observe that there is an increase in the proportion of lymphocytes and of polynuclear cells with one or two nuclei. These investigators have previously reported that the percentage of lymphocytes was increased in incipient, moderately advanced and improving cases and that the percentage of large mononuclears and transitional cells, while within normal limits, was greatest in incipient and improving cases.

The findings of my own series of cases of twenty-one patients are largely in accord with these observations and seem to indicate that:

1. The percentage of hemoglobin (Tallquist scale, controlled by von Fleishl or Dare hemoglobinometer) was reduced. It was increased under treatment. This increase did not seem to depend upon the administration of iron.

2. The erythrocytes were reduced in number They increased under treatment, at least temporarily, irrespective of the lesion.

3. When marked leucocytosis existed, due to toxemia, it was reduced. When the number of leucocytes was below normal, it was increased by treatment.

4. The lymphocytes were usually reduced, and were increased and remained so in those patients who improved. It seems probable that this increase may be considerd as a reliable indication from a prognostic standpoint.

5. The large mononuclears seem to follow the curve of the lymphocytes. It seems probable that they may be included with them, and that their increase or decrease may have a like significance.

6. No conclusion could be drawn from the behavior of the transitionals, eosinophiles or basophiles.

7. The classification and grouping of the polynuclear neutrophiles according to von Arneth's method seems to have some prognostic value.

To summarize, there seems to be, under this method of treatment of pulmonary tuberculosis, and temporarily at least, even in the progressive and fatal types of the disease, a distinct and constant tendency of the cellular elements of the blood and the hemoglobin to approach their normal ratios, and especially for the number of erythrocytes, lymphocytes, and large mononuclears, to be augmented, and for the hemoglobin percentage to be increased.

The most immediate and noticeable effect of treatment was relief of dry, ineffectual cough. In all cases it was relieved and in many patients it was limited to a necessary pulmonary toilet, or disappeared entirely. This seemed to be due to the effect upon the sputum, which was increased in amount and rendered more liquid, so that it was raised with much less difficulty. This effect seemed to be attributable to the action of the pinene on the bronchial mucous membrane. In all cases the complicating bronchitis was diminished or disappeared entirely. While it is recognized that it is not always a trustworthy or permanent indication of improvement, there was noted a marked diminution of tubercle bacilli and the secondary organisms, in the sputum, and in some instances they were absent on several successive examinations, when treatment had been of any duration or continuity.

The temperature, pulse, and respiration of those patients who presented any hope of improvement were reduced and steadied, the curves showing decidedly less variation. In no instance was an acceleration of respiration observed, which might in itself account for improvement, through better aeration of the lungs.

In those patients who improved there was a noticeable diminution of toxemia, indicated by the less frequent occurrence, or disappearance of rigors and hyperidrosis.

The amount of urine and the excretion of urea were increased.

The appetite was in no instance impaired, but rather seemed to be improved.

Partly perhaps from a phychological effect, but certainly also because of the relief of cough, sleep was more continuous, more sound, and more refreshing.

At no time, except when an inferior quality of turpentine was used, were there any evidences of irritation of either the heart, lungs, or kidneys.

The weight increased and the improvement both of the general condition and of the pulmonary lesion seemed to be as rapid and satisfactory as under any other form of treatment, and to compare favorably with that obtained under sanatorium care. Indeed it is noticeable and interesting that all of the patients who were treated in the city made quite as rapid progress here, as afterward in the country, and their improvement here was quite as marked as that of those who began their treatment in the country, or who were under sanatorium care there without treatment. This is true also of those pa-

tients who throughout their treatment have remained in the city. Interruption of the treatment was followed by a diminution of the erythrocytes (Chart 2).

Conclusions.—The researches and their results above reported, while preliminary and incomplete, seem to justify the following conclusions:

1. Oxypinene, prepared by the interaction of pinene vapor and dry ozonized air, possesses the valuable properties of refined and purified oil of turpentine (pinene) minus its undesirable irritating properties. In other words, pinene is modified by oxidation so that it is no longer as penetrating as pinene, nor as quickly absorbed, yet it is capable of producing the same beneficial therapeutic effects.

2. It has marked germicidal effect, *in vitro*, upon *M. pyogenes aureus, B. anthracis, B. typhosus, B. coli communis*, and *B. subtilis*. It also appears to be germicidal to the tubercle bacillus, in sputum.

No experimental work has been done with tubercle *in situ*.

3. When inhaled it does not produce irritation of the respiratory tract, neither does it produce frontal headache or renal irritation, thus decidedly differing from oil of turpentine or pinene.

4. It is a valuable expectorant. It acts as a mildly stimulating diuretic without renal irritation. It seems to stimulate the appetite and digestion and thus to improve nutrition.

5. Its use in the treatment of pulmonary tuberculosis has been beneficial, not so much from its limited bactericidal action upon tubercle bacilli, as by its effect upon the associated organisms and its hematinic power.

6. In subacute and chronic affections of the respiratory system it is indicated as a mild stimulant to the mucous membranes and other tissues.

7. When brought in contact with infected surfaces it inhibits the growth of certain pathogenic microorganisms, and, by its hyperemic property, increases the circulation in the infected area, thus promoting the destruction of such organisms by phagocytosis.

A brief preliminary report upon this subject was made at a stated meeting of the New York County Medical Society on May 27, 1912. Since then the clinical observations noted have been confirmed by several colleagues and in my own hospital service.

BLOOD PRESSURE VARIATIONS, WITH SOME REFERENCE TO TREATMENT.*

By WILLIAM MARTIN, M.D.,

ATLANTIC CITY, N. J.

A CONSIDERATION of the present status of our knowledge of blood pressure shows remarkable advances, which no doubt are due largely to a recognition of its vital importance on the part of the profession as a whole, and also to the perfection of instruments of precision.

A subject so comprehensive as this will occupy too much time if entered into in detail, and, therefore, it is the writer's purpose to deal only with some of the important variations and in a sugges-

*Read before the American Electro-Therapeutic Association, Battle Creek, September 15-17, 1914.

tive way as regards treatment of these varied conditions.

The use of the sphygmomanometer to any extent for practical purposes is confined to the last ten or twelve years, but it has been in general use only during the last four or five years. Even at the present writing blood pressure work has been termed a fad by some, and of no real practical value. It is fair to say in this connection that such pseudo-scientific men are few, and will grow less in number as the years roll on.

One writer of prominence states that Nature often knows what is best for the patient, as regards the proper amount of hypertension, and the "physician should not meddle with Nature's methods until he has good reasons for believing that they have become injurious, or, if we may use such a term, unwise." (Hare: *Therapeutic Gazette*, October 15, 1913.) He states further that "High blood pressure may be said to be, in a majority of instances, as necessary for the maintenance of an approximately normal existence, as cardiac hypertrophy is essential if life is to be maintained in the presence of chronic valvular disease."

There is no question but that a statement of this type may be misleading, unless taken to mean "a hypertension in accord with the physiological lack of exercise, and not considering its cause and correction," as stated in an editorial of the *Journal of Advanced Therapeutics* made in reply to the above. The idea of "hypertension being produced by Nature as a defence does not hold when the cause of this high pressure is toxemia, which does not tend to alleviate the existing condition." To quote further, "in other words, a vicious circle is created in which the poison acting upon the adrenal, or cardiovascular centers, induces a condition without effecting a relief thereby."

The fact that at present we realize the necessity of knowing the amount of cardiovascular compensation in all cases of blood pressure, whether they be high or low, has led to a closer study of all pressures, or in other words, what the systolic, diastolic, and pulse pressures stand for. During the preceding four or five years it has been the custom largely to depend upon one pressure as the guide to prognosis and treatment, some using the systolic, while others argued in favor of the diastolic as being most valuable for these purposes. Gradually as our knowledge has extended the significance of the diastolic and pulse pressures has grown, and from this has come the newer method of estimating all pressures by means of auscultation. In the mercurial instruments this method is much more correct and to be preferred, owing to the sluggish oscillations of the mercurial column.

To read the pulse pressure properly it is essential that both the systolic and diastolic should be correct, and with the mercurial instrument the uncertainty of the diastolic is apparent to all. By the auscultory method the systolic is determined to be at the point where the sound is lost as the bag is inflated, or where it returns on releasing the air. The minimal or diastolic is where the tone begins to diminish in its intensity. Ettinger, after a number of observations, has decided that there are five tone phrases, and the diastolic should be read at the disappearance of all sound. The first mentioned method appears to be the one generally accepted at present. The pulse pressure, being the difference between the two, is easy of determination. The systolic represents the maximum or kinetic energy of the blood column, and the diastolic or minimum the potential energy exerted by the vessel walls; while the difference or pulse pressure "represents the intermittent burden of pressure imposed on the arteries by the heart's energy in systole in order to force the blood toward the periphery and maintain the circulation," as stated by Stone. He further says "the pulse pressure may, therefore, be defined as the amount of pressure exerted by the heart during systole in excess of the diastolic pressure. It measures the excess of dynamic over potential energy."

This then really represents the load of the heart. His studies show that it approximates 50 per cent. of the diastolic pressure under normal conditions. "The systolic and pulse pressures represent myocardial values, while the diastolic pressure represents arterial resistance." These studies show the value and necessity of a careful noting of all pressures instead of a reliance upon either the maximum or minimum for purposes of information relative to cardiovascular conditions, and we are not doing our full duty toward these cases unless we are thorough in this regard.

There are cases of myocardial inefficiency where there may be systolic and diastolic pressures within normal limits, yet the mass movement of the blood be much impaired, as shown clinically by a positive venous pulse dyspnea, cyanosis, and edema, as stated by Hoover.

It has been further demonstrated that persons with high pressure and impaired valves are not seriously embarrassed for a number of years, owing to a compensatory hypertrophy. This is shown by a slightly increased diastolic and a corresponding increase in the pulse pressure, as a compensatory attempt of the heart to adjust itself to new conditions.

There has been much study of late as regards the etiology of hypertension, one theory being that there was an increase of epinephrin in the blood current. While there may be an increased functionating of the adrenals under excitement, this theory has not been sustained by further study. Toxemias of various kinds are perhaps relatively the most frequent causes of hypertension. Contributing factors, such as altered viscosity of the blood, stenosis of arterioles, venous stasis of the liver and other organs, all play their part.

The treatment of simple hypertension without organic changes needs no description here, as it is well known. Of necessity the cause must be removed if possible; therefore, aside from the use of electrical modalities, dietetic and general hygienic regulations must be observed. Of great importance is the care of the eliminations, first of all being that of the bowels.

Hypotension appears to have received less attention than has hypertension, yet its importance is no less; in fact, these cases are ofttimes most urgent for relief and cure. Whether the low tension be from a decompensation or due to a wasting illness, the urgency of the case usually demands that prompt measures be taken to restore organic function, but unfortunately these do not respond so promptly as do the cases of hypertension. There are cases of hypotension that have a low systolic with a correspondingly low diastolic, giving a relative pulse pressure, which may not imply a diminished reserve power of the circulation, but only a condition of lowered vitality with fair organic functioning; but these cases are not relatively frequent. Those that usually come to our notice are of the irregular pres-

sure type, with a low systolic, comparatively high diastolic, and consequently a small pulse pressure that shows myocardial weakness, or perhaps a chronic nephritis or an arteriosclerosis, and these are not favorable prognostically.

When we have the conditions reversed, a comparatively high systolic and a low diastolic, making an excessively large pulse pressure, it may mean one of several things, such as a purely functional derangement, aortic regurgitation with compensation, myocardial degeneration without nephritis or arteriosclerosis, or vasomotor dilatation from any cause.

The diastolic pressure appears to be more stable than the systolic, and less often shows any deviation from the normal without pathological cause. The systolic appears to accommodate itself to the diastolic more readily than the latter to the former. Any wide variation of the diastolic beyond the normal health range throws an overload on the pulse pressure, in order that adequate circulation be sustained. Cardiac depressant drugs may lower the diastolic pressure by diminishing the systolic force of the heart and producing a pulse pressure overload. The vasodilator drugs improve circulation by increasing pulse pressure.

Toxemias may produce hypotension by dilating the blood-vessels and weakening the myocardium, but their effect is largely due to a vascular dilatation, either through the vasomotor center or locally. Chronic tobacco poisoning is one of the causes of persistent low pressure. In early tuberculosis, hypotension is the rule, but if the case is amenable to treatment as it progresses toward recovery, the pressure increases relatively, and may be considered a prognostic guide. In active infections a falling pressure usually means trouble and is another example of the value of a careful study of blood pressure.

Probably one of the most careful and extended studies of a series of cases of hypotension with a definite symptom complex was made by Dr. E. H. Goodman (*Am. Jour. of the Medical Sciences*, April, 1914), who states that all pressures below 120 mm. hg., determined by the auscultory method, should be regarded as low, and he classifies the causes of hypotension as follows: "(1) Acute infections, excepting epidemic cerebrospinal meningitis. (2) Chronic wasting diseases: carcinoma, tuberculosis, cachexia from whatever cause, Addison's disease. (3) Hemorrhage, drugs, chloroform. (4) Nervous diseases: general paralysis of the insane, neurasthenia after epileptic seizures, sometimes in tabetic crises, after lumbar puncture, Grave's disease (at times), osteoarthritis, exhaustion, shock, surgical or anaphylactic. (5) Cardiovascular disease: tachycardia, dilatation of heart, arteriosclerosis (at times), mitral stenosis, decompensatory cardiac lesions. (6) Blood dyscrasias: anemia, polycythemia with splenomegaly. (7) Renal conditions: cyclic albuminuria, nephritis (at times), amyloid disease. (8) Intoxications: alcohol, tobacco, acute adrenal insufficiency. (9) Terminal hypotension preceding death."

There is another type of cases with low pressure that do not show any organic lesions similar to those mentioned earlier in the paper that have as the main symptoms vertigo, headache, and mental and physical tire. These show no evidences of toxemia, and give no history of drug or tobacco poisoning, and, so far as our present knowledge goes, appear to be unexplainable. Such cases usually react favorably under careful regulation of diet, physical exercise, and a general regulation of the mode of living.

A type of pressure that has received less careful study than the aforementioned is that of the irregular form, where the ratio of pressure is different in one arm from the other, and higher lying down than sitting. These are those of vasomotor insufficiency, as described by Abrams and Arnold Snow. Many of these cases have not been recognized in the past, owing to the fact that so few physicians have taken the trouble to take the pressure in both arms and in the prone position. Much additional work is made for the examiner by this method, considering the necessity of registering the three pressures in each arm, both sitting and lying down, but the writer can testify to the diagnostic value of the method from an examination of a fairly large number of cases.

It has been a matter of interest to note the discrepancy of pressures in the two arms, also the increase of pressure in the prone over the sitting posture. This difference in the two arms has been peculiar in another particular. The pressure will frequently change from the lower sitting to the higher lying, in the one arm, while the reverse will be the case with the other arm. When there has been a change in the ratio of the systolic and diastolic under these conditions, the greater range has been observed in the systolic. When with this type of cases there is associated a fairly uniform symtom-complex, they may be termed splanchnic neurasthenics, as designated by Abrams. The liver is usually found to be much enlarged and sensitive to palpation, as is the whole abdomen in some cases; there are gaseous accumulations, while in addition we find nervous depression, very much in proportion to the hepatic engorgement. According to Abrams, there is an exaggeration of the "cardiosplanchnic phenomenon." Quoting further from him, the factor that contributes to this development is "essentially nerve-force lacking in the muscles of the abdomen and in the nervous mechanism which regulates the supply of blood in the abdominal vessels." In these cases, as shown by Dr. Arnold Snow, the pulse irregularity corresponds with the variations of pressure.

The treatment of these cases is largely by intervertebral vibration, the ball electrode being applied to the spaces of the second and third dorsal vertebræ for reversing the pressure and pulse, and to the spaces of the seventh cervical and first dorsal for cardiac insufficiency. According to Abrams, concussion of the spines of the second and eighth dorsal will relieve intraabdominal congestion. In most of these cases the writer has supplemented this treatment by liver thermopenetration followed by the wave current, which has given happy results.

In all cases that come under our jurisdiction it is essential that due care be taken to ferret out the causative factor or factors, whether they be errors of diet, faulty living, diseases, or whatever, and do our best to correct and eliminate them. Constipation offers one of the problems in most of these cases, as it is an accompaniment, if not a factor, in the majority of cases. Corrective measures must be taken, therefore, either as regards enemas or by the use of mechanical agents, such as mineral oil or agar-agar, together with physical measures as are suited to each case.

In hypotension it is equally important that the cause be found and eliminated, but there are often different problems to be met. As regards toxic

causes, the same care can be used as in other cases.

When there is decompensation efforts must be directed toward improving myocardial and cardiovascular tone as one of the first steps toward relief and cure. In some cases the wave current will supply this need, and in others the resonator effleuve will meet the requirements. As each case requires individual study, no one can lay down a hard and fast rule by which we can treat, but constitutional up-building must be the keynote of the situation.

In considering a subject of this kind before such a body of men the writer is fully aware that he can offer little that is new, but there is always an advantage to all in having even the most ordinary and trite subjects rehearsed from time to time. But at this time it is the writer's main thought to emphasize the importance of greater care in our daily routine of pressure work, and particularly in the estimation of the three pressures, in order that we may have a full scientific knowledge of our work.

A CASE OF GUMMA OF THE LOWER EYELID.

By ANDREW J. GILMOUR, PH.B., M.D.,

NEW YORK.

CONSULTING DERMATOLOGIST, MANHATTAN STATE HOSPITAL; ASSISTING ATTENDING DERMATOLOGIST, NEW YORK CITY CHILDREN'S HOSPITAL AND SCHOOLS.

M. F., female; married; white; age 32 years; nativity, Austria; occupation, actress. Fourteen years previous to June 18, 1914, the date when the patient was first seen, she contracted lues and was treated for two years by a well-known Chicago specialist who told her she was cured. After that until six years ago the patient was in perfect health at which time "ulcerated sores" appeared on her body. Various doctors were consulted who treated the matter lightly and gave only salves which cleared up these lesions on several occasions.

Again a year ago a sore appeared on the back of the neck which "ran around the head, neck, and ears." Again the patient was told there was nothing the matter with the blood and this lesion healed under the use of ointments without any internal medication.

Seven months ago a sore came over the right shoulder blade and later ulcerated. This now shows as an ulcerating papulo-serpiginous syphilide which has healed as it advanced and is still progressing. I quote the written history that was sent me by the patient: "I awoke one morning the latter part of April, 1914, to find my eye slightly swollen and itchy. On examining it I found a small red pimple with a yellow center. In a couple of days pus began running from it and the sore was creeping up toward the edge of the eyelid and eating along the lid toward my nose. It became very painful and I consulted a private doctor who diagnosed it as a specific ulcer and confirmed the diagnosis by a Wassermann test. He sent me to the clinic."

Physical examination shows an ulcer three-quarters of an inch long along the outer half of the edge of the lower lid of the right eye. It is slightly purulent showing little tendency toward healing.

Treatment.—Locally an ointment of 1 grain of yellow oxide of mercury to 1 dram of vaseline was used on the eyelid.

July 8, 1914.—Since first seen the patient has had two injections in the vein of 0.2 gram of salvarsan and three injections of 1 grain each of mercury salicylate. This was sufficient to heal the lesion on the eye as also the one on the back.

133 East Fifty-seventh Street.

Medicolegal Notes.

Agreements Not to Practice—Right to Injunction.—Suit was brought in equity for dissolution of a partnership relation between physicians, and for the enforcement of a restrictive covenant contained in the partnership agreement, by the terms of which the defendant bound himself, in case the partnership was terminated because of violation of the contract by him, to refrain from practising his profession in Atlantic City for a period of three years thereafter. The plaintiff, Dr. Marvel, began the practice of medicine in Atlantic City about 1884. His practice gradually grew to such an extent that in 1905 it became necessary for him to employ an assistant. The defendant, Dr. Jonah, who had graduated from a medical college five years before, was selected by him for that position. In 1906 Dr. Marvel found it desirable to employ a second assistant, and took in Dr. Durand. In 1908 Dr. Marvel and Dr. Jonah entered into a parole partnership agreement, which, in 1910, was superseded by a written agreement. The evidence showed that the purpose of Dr. Marvel in having the restrictive covenant put in the partnership agreement was to prevent the younger members of the firm, after having been brought into association with his patients, as his representatives, from setting up an independent practice in Atlantic City, and taking with them such patients, or any of them. The New Jersey Court of Chancery denied relief, on the ground that it would be unjust and unnecessarily oppressive to enforce the restrictive covenant. This conclusion was apparently based upon the idea that, although the independent practice of his profession in Atlantic City by Dr. Jonah would result in the loss of patients by Dr. Marvel, yet, even after such loss, the latter's practice would still be so large as to be beyond the ability to cope with it without the assistance of others, and, consequently, that the restraint sought by him against Dr. Jonah would be of little value to him if granted. On appeal it was held that Dr. Marvel was entitled to an injunction. It was said by the court that it would not do to say that a man who has built up a business so extensive that he cannot handle it without the aid of a staff of assistants suffers no loss or injury by its diminution in volume to such an extent that he no longer needs assistance to carry it on, provided that what remains of it is sufficient fully to occupy his own time. But the complainant's right to an injunction was held not to depend upon the extent of the injury to his business which would result from the violation of the covenant. It was sufficient that the injury be material. Where there is an express covenant, and an uncontroverted injury arising from the breach of it, equity will grant an injunction to restrain such breach, where the injury arising therefrom cannot be repaired, nor estimated in dollars and cents. The damages arising from the breach of such a covenant would be continuing, accruing from day to day, and it would be impossible to ascertain the money loss sustained by Dr. Marvel therefrom with anything approaching accuracy. A suit at law, therefore, would afford no adequate remedy; and when this is the case a Court of Chancery should enforce the covenant by granting an injunction to prevent the breach of it. Three judges dissented on the ground that, while it was proper that Dr. Jonah should be prevented from taking Dr. Marvel's patients, the present covenant penalized Dr. Jonah by prohibiting him from practising, not only among such patients of Dr. Marvel, but also among the hundreds of thousands of other persons who annually visit Atlantic City. —Marvel v. Jonah, New Jersey Court of Errors and Appeals, 90 Atl. 1004.

MEDICAL RECORD.

AMERICA'S MEDICAL SUPREMACY.

AN editorial writer in a recent issue of the *Long Island Medical Journal* expresses the fear, or the threat, that the American post graduate medical student will not be persona grata in Germany and Austria in future if the people of this country do not speedily shift their sympathy from the Allies to the Austro-Germans. We do not share the apprehension of our esteemed contemporary, for by the time this war is over American dollars will look as big as cartwheels to a Privatdozent in Vienna or Berlin, and his only distress will be to find that they are not to be picked up so readily as they were before the politicians brought on the war and spoiled his market. Spoiled his market will surely be if the war lasts over another winter, for American students have been discovering their own country this year and are now learning by necessity what they have often been told but refused to believe, that the facilities for post-graduate medical instruction are as good in half a dozen cities of the United States as they are in any city in Europe. And why should they not be? The best surgeons in the world are Americans; internal medicine is nowhere further advanced than it is here; some of the greatest discoveries in medical science have been made in this country; nowhere are the specialties studied and practised with greater zeal and more brilliant success than among us, and our research laboratories, though of more recent growth, need not fear comparison with those of Europe.

We reached this point while Europe was still at peace and the universities in every country were teeming with scientific activity. Now all the young blood of the laboratories has been drawn into the army and much of it has reddened the snows of Poland, France, and Belgium, the universities and laboratories meanwhile marking time with the problems of military medicine, with no opportunity for following the antebellum lines of scientific research. Here, however, study and research are unaffected by the transatlantic insanity, and if with the advantage of a nearly even start America does not now leap ahead and take admittedly the first rank in the world of medicine, it will have lost the opportunity of a century. But it will not lose it. Already during the last decade foreign medical men have been coming here in increasing numbers to observe our progress and study our methods, and if these scientific pilgrimages from the East to the West do not increase in number and volume when the war is over and the former combatants have recovered their breath and earned the wherewithal to travel, it will be a strange thing and discreditable to America. There will, of course, be many Americans going to Europe, for one can always gain something by observing things from a new angle, even if this angle is no better than one's own, but the number of such will be far smaller than before, and the average American will be content to get his post-graduate instruction in his own country, for he will know that he cannot get better, if as good, in any other land.

ANALGESIA AND ANESTHESIA IN LABOR.

THE undue prominence given to the Freiburg method by an enterprising though questionable publicity has tended to divert attention from the traditional and probably little less effective methods of subduing the pangs of childbirth. Edwin P. Davis (*American Journal of the Medical Sciences*, January, 1915) finds that the experience of various American observers in the use of scopolamine-morphine seminarcosis is not as yet sufficient to warrant a decision as to the efficacy of this procedure. In his own hands the use of these drugs has produced severe headache and vomiting in the mother.

In the management of labor Davis has adopted a procedure, the results of which are apparently safer and none the less certain than those of "dämmerschlaf." During the first stage of labor the suffering is allayed by thoroughly emptying the bowel by means of a hot, high enema, by frequent emptying of the urinary bladder, by the use of bromides by the mouth, by enforcing quiet, and by securing the comfort of the patient. If these measures fail and if the patient is threatened with exhaustion from irritation, morphine and atropine should be given hypodermically.

During the second stage of labor, if there is considerable suffering and if the uterine contractions are irregular, there are administered hypodermically strychnine 1/60 to 1/30 grain, digitalin 1/100 to 1/50 grain, and codeine ¼ to ½ grain. These may be repeated in an hour if necessary. When expulsion is imminent the patient is made to inhale a small amount of ether at the height of a pain, and this anesthetic is given freely and quickly at the moment of expulsion. The results of this method of treatment are that the patient does not know when the child was born, nor does she recall any sensation of suffering. Shock, headache, and nausea are absent, and there is no bad effect upon the child.

One important advantage of this method of treatment is that it is adapted for routine private practice and requires no especial degree of skill or vigilance. The author condemns the use of chloroform on the grounds that this tends to produce uterine relaxation and is more apt to be followed by hemorrhage than ether is. Although the fetus is affected by large doses of morphine and prolonged anesthesia, no serious result is to be feared from the ordinary and careful use of morphine and ether.

The Antinarcotic Law.

The attention of our readers is called to the fact that the so-called Harrison Antinarcotic Law goes into effect on March 1, 1915, and any physician who violates, knowingly or unknowingly, any of its provisions after that date will incur the penalty of a fine of $2,000 or five years' imprisonment or both. It therefore behooves everyone to acquaint himself with the law and to obey its irksome provisions if he would continue to practise his profession in this free land of ours. In brief, the law commands that every physician who would buy, sell, give away, or *have in his possession* any "opium or coca leaves, or any compound, manufacture, salt, derivation, or preparation thereof," shall register his name and office address with the collector of internal revenue of his district and shall pay to said collector an annual tax of one dollar. A registered physician may prescribe any of these drugs, but the prescription must be signed and dated by him and must bear the name of the person for whom the drug is prescribed; he may also dispense or give to a patient any of these drugs, but must keep a record showing the amount of such drugs dispensed or given away and the name of the patient to whom they are given, "except such as may be dispensed or distributed to a patient upon whom such physician . . . . shall personally attend." As a physician is not likely to have a patient whom he does not personally attend, unless he is doing a mail order business, this exception apparently frees him from the necessity of keeping records of his dispensing; he had better keep them, however, for there is no telling what interpretation some idiot official may put upon this section of the act. But while he may possibly be free to prescribe or dispense, he cannot purchase any of the taboo drugs without filling out a duplicate order upon a form supplied by the collector at a further expense of one dollar a hundred. This order must be kept by the vendor, and the duplicate by the buyer, for a period of two years and must be shown on demand to any inquisitive "officer, agent, or employee of the Treasury Department" or to any State or municipal official charged with the enforcement of a law regulating the sale or prescription of these drugs. And so on March 1, 1915, the physician too will enter upon the enjoyment of his new freedom, at one dollar a year and order blanks extra.

von Mayer and the Doctrine of the Conservation of Energy.

Robert von Mayer, the German protagonist and claimant of first honors for the discovery of the persistence of energy would have been one hundred years old had he survived to 1914. His death took place in 1878, but his activities are frequently quoted to show what can be done by young men who are handicapped in various ways. In a communication to the *Deutsche medizinische Wochenschrift* for November 26, Mamlock gives credit to the American Count Rumford for pioneer studies in this direction, he having shown plainly that "heat is a mode of motion." In 1842 Mayer upheld the notion of the persistence and transformation of energy. Helmholtz later sought to show that such a law was merely a corollary from Newton's teachings on motion. Mayer continued to defend his views as originally stated, but he was doubtless a victim of psychopathic constitution of direct inheritance. Upon this substratum he developed manic-depressive insanity during the very years in which he was most active polemically. He was undeceived in many respects as to certain phases of his doctrine. In 1869 he was ceremoniously given credit in Germany for his great discovery. Amid all his other troubles he had to contest his priority rights with the English physicist Joule, who receives but scanty mention in this connection. It was during the beginning of the Mayer-Joule controversy that Mayer began to suffer from nervous disorders.

War Aneurysms.

Professor Bier is at the head of the medical staff of the German navy, but owing to the inactivity of the latter, has turned his attention to the treatment of aneurysms among the wounded (*Berliner klinische Wochenschrift*, December 14). In the past two months he has performed 43 operations on 42 patients for aneurysms of the larger vessels (28) and arteriovenous aneurysms. Traumatic aneurysms, he says, are really false aneurysms. First there is a perforation of the artery, a form of hematoma resulting. The cavities formed may equal a child's head in size, and the method of their genesis is not apparent. The projectile first makes a wound cavity in which the blood escapes and clots. A bowl-shaped cavity results, varying much in size and location. The margins are constituted of muscle and fascia. These aneurysms pulsate. In time the blood is absorbed and the sac organizes. The arteriovenous aneurysms form when both kinds of vessels are wounded. Blood flows from arteries to veins. Direct adhesion or varicosities may form. Fourteen cases were treated by the old method of ligation, while in the balance suture or venous transplantation was employed. Two patients with intrathoracic subclavian aneurysm were lost, and there were two technical failures in suture cases which required secondary intervention.

Chemical Disinfection of Water.

Although in many parts of this country the public water supply is as good as anywhere on earth, in other places it is not safeguarded as it should be, and, as Earle B. Phelps says in *Public Health Reports*, Oct. 9, 1914, writing on chemical disinfection of water, there are few untreated water supplies in the United States to-day which are so well protected that they do not at times show evidences of pollution. Consequently, the chemical disinfection of water is not only of use in large and small cities throughout the country, but can be employed in emergencies on quite a small scale. Phelps refers to the three agencies for the chemical disinfection of water which have alone thus far proved satisfactory, namely, ozone, hypochlorite of calcium, and gaseous chlorine. The hypochlorite process is one not largely employed, although according to Phelps, the proper application to a water of the requisite qualities of this disinfectant will bring about a practically complete removal of pathogenic organisms without affecting the water to any noticeable extent. But, in order to obtain these results the proper quantity of the disinfectant must be applied in the proper way, and therefore in any important installation the services of a qualified expert who had experience in this particular line are almost indispensable. For the purification of

smaller water supplies Phelps gives clear directions as to how to proceed in installing small hypochlorite plants. It appears from his description that what he terms "first aid" remedies can be applied to a polluted water with a quite simple paraphernalia, and by the exercise of common sense, such a hypochlorite installation can be provided by means of which the water supply of any community can be absolutely safeguarded within a few hours after commencing work.

An Early Symptom in Intestinal Obstruction.

The importance of an early diagnosis in this condition is fully emphasized by the statistics of Naunyn, which show that 70 per cent. of the patients that are operated upon within the first forty-eight hours survive, whereas only 34 per cent. survive if operated upon on the third day. The diagnosis of intestinal obstruction is usually based upon the presence of four symptoms: abdominal pain, absolute retention of feces and gas, tympanites, and stercoraceous vomiting. None of these symptoms is by itself pathognomonic. The fecal and gaseous obstruction and the fecal vomiting may be relatively late manifestations, and if waited for in every instance before a diagnosis is made the safety of the patient may be compromised. Pasquale Cataldi (*Il Policlinico,* December 13, 1914), calls attention to dilatation of the stomach as a constant and early manifestation of intestinal obstruction. In the four cases which he reports this symptom was quite prominent. Without regarding it as pathognomonic, the author attributes considerable diagnostic importance to this manifestation, particularly when it is associated with or followed by the other well-known symptoms of intestinal obstruction. He believes that the dilatation of the stomach is of purely reflex nervous origin, that is to say it is a paresis of the stomach caused by excitation of the abdominal sympathetic.

The Vesalius Quadricentennial in Berlin.

The birth of Vesalius four hundred years ago was honored by the united medical societies under the auspices of the Berlin Medical Society on December 23 (*Berliner klinische Wochenschrift,* January 11). The papers of the evening were by Hans Virchow and Holländer the antiquarian. Doubtless the inception of the movement antedated the war and the conquest of Belgium and the latter event was not allowed to dim in the least the brightness of the meeting. Vesalius was a citizen of conquered Belgium, a fact several times mentioned, but with the added assertion that he was born at Wesel of German parents, which may be true but will be news to many of the great anatomist's biographers. It was proposed and carried that on December 31, the actual birthday, the societies cause a laurel wreath to be hung upon the Vesalius memorial in Brussels. Among the wealth of biographical details, and enumeration of honors which belong to Vesalius, we fail to note in the report of the meeting any allusion to the fact that he was educated at the University of Louvain. This omission may, of course, have been an oversight, but to have mentioned his alma mater, whether with or without some expression of regret, would perhaps have thrown a shadow upon the success of the meeting.

The Pathogenesis of Peptic Ulcer.

In 1913, Corica, in studying the behavior of the hemolymphatic system in the experimental anemia produced by the injection of pyrodine into dogs, discovered the presence of ulcers in the stomach and duodenum of these animals. Further investigation along this line was carried out by R. Crescimone and B. Anglesio (*Riforma Medica,* November 21, 1914) in two sets of experiments. In the first of these the animals were subjected to experimental pyrodine anemia. In the second set this was preceded by bilateral subdiaphragmatic resection of the vagi. The results of these investigations may be summarized as follows: The prolonged and slow poisoning by means of pyrodine leads to the death of the animal and in fifteen out of sixteen instances gastric and duodenal ulcerations are present. These lesions are more pronounced if there has been a preceding subdiaphragmatic section of the vagi. The gross and microscopic appearances of the ulcers are identical with those of the typical peptic ulcers in the human being. The origin of gastric and duodenal ulcer is attributed in large part to a diminution in the resistance of the tissues by virtue of a deficiency in the antiproteolytic ferments, a sequence which may readily occur in the case of the peptic ulcers occurring in anemia.

News of the Week.

For the Relief of Belgian Physicians.—The treasurer of the Committee of American Physicians for the Aid of the Belgian Profession reports the following contributions received during the week ending February 6, 1915:

Dr. Willard Bartlett, St. Louis, Mo.	$10.00
Dr. M. Manges, New York, N. Y.	15.00
Dr. G. D. Hale, P. A. Surg, U. S. N., San Francisco, Cal	10.00
Dr. Alfred Wiener, New York, N. Y.	10.00
Dr. John Woodman, New York, N. Y.	5.00
Dr. Robert T. Frank, New York, N. Y.	10.00
Cash—B., Pittsburgh, Pa.	10.00
Dr. R. O. Raymond, Flagstaff, Ariz.	10.00
Dr. A. Hymanson, New York, N. Y.	5.00
Dr. Mazyck P. Ravenel, Columbia, Mo.	15.00
Oklahoma State Med. Assoc., Muskogee, Okla.	100.00
Dr. H. H. Sherk, Pasadena, Cal.	25.00
Dr. James Williamson, Philadelphia, Pa.	5.00
Dr. J. S. Kauffman, Blue Island, Ill.	5.00
Dr. John P. Treanor, Dorchester, Mass.	10.00
The Clinical Club of Albany, Albany, N. Y.	25.00
Dr. Thomas J. Watkins, Chicago, Ill.	50.00
Dr. H. E. Oesterling, Wheeling, W. Va.	10.00
Dr. Leslie W. Schwab, Chicago, Ill.	2.00
Dr. A. Howard Smith, Marietta, Ohio.	5.00
Dr. Woodson H. Taulbee, Maysville, Ky.	5.00
Total	$362.00
Previously reported receipts	2,166.00
Grand Total	$2,528.00
Previously reported disbursements	$2,090.00
Disbursements week ending Feb. 6th	440.00
Total disbursements	2,530.00
Deficit	$2.00

Dr. Lewis S. McMurtry of Louisville, Ky., and Dr. Charles A. L. Reed of Cincinnati, Ohio, have consented to become members of the Committee of American Physicians for the Aid of the Belgian Profession. At the request of the treasurer the executive committee has arranged to have a quarterly audit of his accounts. The first audit will be made about March 20, 1915.

The Health of the Canal Zone.—The report of Dr. Charles F. Mason, Chief Health Officer of the Canal Zone, for November states that there were five deaths from disease among the employees during the week, the rate being 1.61 per thousand as compared with 4.68 for the preceding month and 4.89 for the corresponding month last year. Among the residents of the Zone there were 39 deaths

from disease, giving a rate of 12.66 per thousand, as compared with 13.85 for the preceding month and 15.82 for the corresponding month last year. In Panama City the death rate was 33.20 per thousand, as compared with 32.00 for the preceding month and 37.14 for the corresponding month last year.

The Death Rate of New York.—During the week ending January 30 there were 1,460 deaths in this city as against 1,628 during the corresponding week last year. The death rate for the first five weeks of this year was 14.08 per 1,000 of the population as against a rate for the corresponding period of 14.75, a decrease of .67 of a point.

Street Accidents.—The National Highways Protective Society reports that there was a reduction of 30 per cent. in fatal accidents in the streets of this city in January of this year as compared with the same month in 1914. During the month sixteen children lost their lives, fourteen being killed by automobiles, one by trolley, and one by wagon. The total number of persons killed was thirty-one, of which number automobiles killed twenty-three, trolleys four, and wagons four. The number of persons killed on the streets and highways of New York State, outside of New York City, during the past month was eleven. Automobiles caused the death of seven and trolleys four, as compared with five by automobiles, five by trolleys, and one by wagon in January, 1915. In New Jersey thirteen persons were killed by automobiles, as compared with eight during the month of January, 1914. Nine persons were killed at railroad grade crossings in New York and six in New Jersey during the month.

An American Doctor Insulted for Speaking English.—An Associated Press report from Vienna states that Dr. Frank C. Davis, president of the American Medical Association of Vienna, has addressed a complaint to the Vienna *Neue Freie Presse* in which he says that recently he has been molested three times in the Austrian capital because he spoke English. In one instance, he says, a woman wanted him ejected from a street car, and in another case the proprietor of a café ordered him to leave the establishment.

Working of the Eugenics Law.—The Wisconsin State Board of Health in its annual report shows that since the eugenics law went into effect January 1, 1914, the number of marriages in Wisconsin dropped 3.800. In 1913 there were 21,052 marriages and in 1914 only 17,252.

The Report of the New York City Health Commissioner for 1914, recently issued, shows that there was a notable decrease in infant mortality, that the death rate was the lowest ever recorded in New York, that sanitary conditions have been improved generally. There were 5,513 more births in 1914 than in 1913, and that 1,784 more marriages were reported than in 1913.

The old sanitary code of the city was revised, and a number of new amendments were adopted, among them being the prohibition of the sale of bichloride of mercury except upon a physician's prescription. Three deaths from rabies occurred during the year, and 852 persons received Pasteur treatment. In a letter to Dr. Goldwater, expressing his satisfaction with the excellent work of the Health Department during the year, Mayor Mitchel wrote: The taxpayers ought to know that out of its appropriations for 1914 the Department of Health turned back into the city treasury the sum of $170,000; that the city's milk supply is now protected by the most complete municipal inspection system in the country; that the more important officials of the department are now giving their undivided time to its work; that private physicians are now sharing the medical inspection of school children, thus reducing the municipal cost of this work; that a bureau of public health education has fulfilled its promise to put the Bureau of Food Inspection on an effective footing, and that the department is engaged in numerous other activities which are directly and indirectly productive of health and welfare.

Dr. John H. Huddleston has been elected chairman of the medical board of the Willard Parker and Riverside Hospitals of the New York City Department of Health to succeed Dr. John Winters Brannan, who has resigned after many years' service. Dr. Brannan retains his association with the hospitals as consulting physician.

Dinner to General Gorgas.—The local Medical Reserve Corps, U. S. A., gave a banquet last week at the McAlpin Hotel in honor of Surgeon-General William C. Gorgas. Dr. Victor C. Vaughan of Ann Arbor, Mich., president of the American Medical Association, Col. L. Merwin Maus and Col. A. E. Bradley of the U. S. Army Medical Corps, Col. Richards of the Army War College, Dr. John A. Wyeth, and Dr. George Henry Fox were among those present.

Examination of Candidates for the United States Public Health Service.—Boards of commissioned medical officers will be convened to meet in Washington, D. C., Boston, Mass., New York, Chicago, St. Louis, Louisville, New Orleans and San Francisco on Monday, March 8, 1915, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service. Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and must furnish testimonials from two responsible persons as to their professional and moral character. Candidates must have had one year's hospital experience or two years' professional work. Successful candidates will be numbered according to their atttainments on examination, and will be commissioned in the same order. They will receive early appointments. After four years' service assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Assistant surgeons receive $2,000, passed assistant surgeons $2,400, surgeons $3,000, senior surgeons $3,500, and assistant surgeon generals $4,000 a year. When quarters are not provided, commutation at the rate of $30, $40, and $50 a month, according to the grade, is allowed. All grades receive longevity pay, 10 per cent. in addition to the regular salary for every five years up to 40 per cent. after twenty years' service. Any one wishing to come up for this examination should address the Surgeon-General, Public Health Service, Washington, D. C.

Civil Service Examinations.—An examination will be held on March 2 for positions in the Philippine Service as follows: Bacteriologist and pathologist, salary $2,000-$2,500; medical inspector and surgeon, salary $3,000; specialist in mental and nervous diseases, salary $3,500. The examinations are open to all male graduates of a reputable medical school who are citizens of the United States and who meet the special requirements as regards experience, etc., in each case. Persons

wishing to take any of these examinations should at once apply for Forms B. I. A. 2 and 2095, stating the title of the examination for which the forms are desired, to the United States Civil Service Commission, Washington, D. C.; the secretary of the United States Civil Service Board, postoffice, Boston, Mass., Philadelphia, Pa., Atlanta, Ga., Cincinnati, Ohio, Chicago, Ill., St. Paul, Minn., Seattle, Wash., San Francisco, Cal.; custom house, New York, N. Y., New Orleans, La., Honolulu, Hawaii; old custom house, St. Louis, Mo.; or to the chairman of the Porto Rican Civil Service Commission, San Juan, P. R. No application will be accepted unless properly executed, including the medical certificate, and filed with the Commission at Washington, with the material required, prior to the hour of closing business on March 2, 1915.

The New York State Civil Service Commission announces an examination in February 27 for physicians, Richmond County Sheriff's office, salary $750. Candidates must be legally licensed medical practitioners and residents of Richmond county for the past three months. Any one wishing to take this examination should write for application blank to the State Civil Service Commission, Albany, N. Y.

Mayo Research Foundation of the University of Minnesota.—A plan of Drs. William J. and Charles H. Mayo of Rochester, Minn., to establish a $1,000,000 foundation for medical research in connection with the University of Minnesota under certain restrictions has been approved by the faculty of the medical department and it now is under consideration by the University Medical College Advisory Board. The interest of the fund will be used in research work at Rochester by graduates of the university medical department.

Typhoid Fever in a Hospital.—Twenty of the doctors, nurses, and employees of the Sloane Maternity Hospital in this city have suffered from typhoid fever since the beginning of the year. None of the patients has been attacked and the origin of the outbreak has not been ascertained; no typhoid carrier has been discovered among the kitchen and dining-room staffs.

Damages for Injury to the Hand.—A Chicago physician who was thrown out of his berth in a sleeping car on an Indiana train has received $32,500 for injuries to his hand, which he claimed would interfere with his work as a surgeon. Of the total amount $15,000 was paid by accident insurance companies, the balance by the railway company.

More Cigarette Legislation.—A bill has been introduced into the Wisconsin legislature providing that no educational institution of any kind which is supported in whole or in part by public money shall employ a teacher who smokes cigarettes, and that no such institution shall grant a diploma or certificate of education to any one who smokes cigarettes.

War on Jersey Mosquitos.—The Bergen County Board of Freeholders has appropriated $14,000 to aid in mosquito extermination. Representatives from the New Jersey State Commission appealed to the board, asserting that the neighboring counties of Hudson, Essex, and Union were complaining because of Bergen's seeming indifference. Last year the board appropriated only $800.

Torpedoing a Hospital Ship.—The officers of the British hospital ship *Asturias* report that on February 1 when the vessel was approaching Havre and was fifteen miles out, with a staff of doctors and nurses aboard, a German submarine was sighted, whereupon the vessel hastened for port without waiting for a pilot. It was full daylight, the men say, and the submarine could not possibly have mistaken the character of the hospital ship, which is painted white and carries a green stripe and red crosses, as provided by The Hague Convention. A torpedo was seen rushing toward the vessel. The navigating officer promptly swung the ship around. His action alone saved the *Asturias*, according to those aboard, the torpedo dashing past, a few yards astern.

Post Graduate Instruction in Contagious Disease.—The Department of Health has under consideration the inauguration of a series of clinics in contagious diseases, to be held in the hospitals of the Department of Health, and to be open to graduates in medicine practising in the City of New York. In arranging for the course it will be helpful to know to what extent physicians will interest themselves in it, and physicians who desire to take advantage of this opportunity are therefore requested to communicate promptly with the Commissioner of Health.

Public Health Exhibit.—The Department of Public Health of the American Museum of Natural History is at present engaged in the preparation of a special exhibit of military hygiene and sanitation, dealing with the health of armies, the hygiene of the individual soldier, and the general problems of camp sanitation. A number of new exhibits illustrative of insect-borne diseases were added to the department's display during 1914, the most important single exhibit being a model of the flea (carrier of bubonic plague) 1,728,000 times natural size, prepared by Mr. Ignaz Matausch.—*Science.*

The Massachusetts Board of Health.—The Governor of Massachusetts has appointed the following members of the State Board of Health to serve under the State Health Commissioner, Dr. Allan McLaughlin: X. H. Goodnough, chief engineer, director of the division of sanitary engineering; H. W. Clark, chemist, director of the division of water and sewerage laboratories; William C. Hanson, director of the division of records and accounts; Hermann C. Lythgoe, director of the division of food and drugs; Prof. Milton J. Rosenau, pathologist; Dr. Eugene R. Kelly of Seattle, director of communicable diseases.

Medical Society Elections. — The Fayette County (Ky.) Medical Society, meeting in Lexington on December 15, elected the following officers: *President*, Dr. John C. Lewis; *Vice-President*, Dr. Porter Prather; *Secretary-Treasurer*, Dr. L. C. Redmon; *Delegate to the State Society*, Dr. C. A. Vance; *Censor*, Dr. W. O. Bullock.

The Jefferson County (Ky.) Medical Society elected the following officers at a meeting held December 21: *President*, Dr. Ap Morgan Vance; *First Vice-President*, Dr. R. Lindsey Ireland; *Second Vice-President* Dr. Jethra Hancock; *Treasurer*, Dr. Bernard J. O'Connor; *Judiciary Councillors*, Dr. E. S. Allen and Dr. Claude G. Hoffman.

The Henderson County (Ky.) Medical Society elected the following officers on December 15: *President*, Dr. Archibald Dixon; *Vice-President*, Dr. J. H. Letcher; *Secretary*, Dr. Peyton Ligon.

The Salt Lake County (Utah) Medical Society elected the following officers at a meeting held December 16: *President*, Dr. R. W. Tyndale; *Vice-President*, Dr. W. F. Beer; *Secretary*, Dr. R.

W. Ashley; *Treasurer*, Dr. George F. Roberts; *Censors*, Drs. J. N. Harrison, S. L. Richards, and R. R. Hampton.

The Pulaski County (Ark.) Medical Society, at a meeting in Little Rock on December 16, elected the following officers: *President*, Dr. J. B. Dooley; *Vice-President*, Dr. A. M. Zell; *Secretary*, Dr. S. M. Gates; *Treasurer*, Dr. W. R. Bathurst; *Member of the Board of Censors*, Dr. A. E. Harris.

The Muskogee County (Okla.) Medical Society elected the following officers at a meeting held December 14: *President*, Dr. Benjamin H. Brown; *Vice-President*, Dr. M. K. Thompson; *Secretary-Treasurer*, Dr. H. P. Ballantyne; *Censors*, Drs. J. S. Vittum and I. B. Oldham.

The Reno County (Kan.) Medical Society, at a meeting in Hutchinson on December 22, elected the following officers: *President*, Dr. Fred Forney of Hutchinson; *Vice-President*, Dr. W. C. Bondurant of Partridge; *Secretary-Treasurer*, Dr. W. F. Schoor of Hutchinson; *Delegate to the State Society*, Dr. C. L. McKittrick, *Censors*, Drs. Heylmun and Seehorn.

The Story County (Ia.) Medical Association elected the following officers at a meeting held December 18 at Ames: *President*, Dr. Hearem of Story City; *Vice-President*, Dr. B. G. Dyer of Ames; *Secretary and Treasurer*, Dr. F. S. Smith of Nevada; *Delegate to State Association*, Dr. B. G. Dyer of Ames; *Alternate*, Dr. D. M. Christ.

The Union County (Ia.) Medical Society, at the annual meeting held in Creston on December 23, elected the following officers: *President*, Dr. J. Fry; *Vice-President*, Dr. W. K. Keith; *Secretary-Treasurer*, Dr. T. V. Golden; *Censor*, Dr. O. S. Barber; *Delegate to State Society*, Dr. J. W. Reynolds; *Alternate*, Dr. W. K. Keith.

The Ashland County (Wis.) Medical Society elected the following officers at a meeting held December 21: *President*, Dr. M. S. Hosmer; *Vice-President*, Dr. J. V. Wenzel; *Secretary and Treasurer*, Dr. C. J. Smiles.

The Will County (Ill.) Medical Association, at the annual meeting held in Joliet on December 15, elected the following officers: *President*, Dr. A. L. Shreffler; *Vice-President*, Dr. W. R. Fletcher; *Secretary-Treasurer*, Dr. Marion K. Bowles; *Delegate to State Association*; Dr. W. A. Curtiss; *Alternate*, Dr. Marion K. Bowles.

The Van Wert County (Ohio) Medical Society held its annual meeting at Van Wert on December 10 and elected the following officers: *President*, Dr. M. S. Cramer; *Vice-President*, Dr. Robert C. Flemming; *Secretary and Treasurer*, Dr. C. G. Church; *Delegate to State Society*, Dr. B. L. Good.

The Medical Society of the County of Lewis (N. Y.) elected the following officers at the annual meeting held at Watertown, December 21: *President*, Dr. Paul H. von Zierolshofen of Croghan; *Vice-President*, Dr. Cyrus W. Culver, Lowville; *Treasurer*, Dr. Demton of Turin; *Secretary*, Dr. E. N. K. Mears of Lowville.

Obituary Notes.—Dr. Louis A. Rodenstein of New York, a graduate of the Department of Medicine of the University of Pennsylvania, Philadelphia, in 1859, a veteran of the Civil War, and formerly a surgeon in the New York Police Department, died at his home on January 31, aged 79 years.

Dr. Charles T. Montgomery of Saugerties, N. Y., a graduate of the Albany Medical College in 1874, and a member of the New York State and Ulster County Medical Societies, died at his home on January 15, aged 65 years.

Dr. F. Robert Boyd of St. Louis, Mo., a graduate of the Cleveland College of Physicians and Surgeons, Cleveland, O., in 1886, and a member of the American Medical Association, the Missouri State Medical Association, the St. Louis City Medical Society, and the American Electrotherapeutic Association, died at his home, after a short illness, on January 2, aged 63 years.

Dr. C. C. Donovan, Jr., of Scranton, Pa., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1913, died at his home after a long illness, on January 8, aged 24 years.

Dr. Isaac Leopold of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1886, died recently at his home, aged 50 years. Dr. Leopold was one of the organizers of the Jewish Maternity Hospital of Philadelphia and the Eaglesville Sanitarium for Consumptives, and medical director of the Seaside Home for Jewish Children, and a member of the staff of the Kensington Home for Women. He was also a member of the American Medical Association, the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, the Philadelphia Pediatric Society, and the Philadelphia Pathological Society.

Dr. William Boddie Rogers of Memphis, Tenn., a graduate of the Bellevue Hospital Medical College, New York, in 1878, for twenty-six years dean of the Memphis Hospital Medical College and professor of the principles and practice of surgery and clinical surgery, and a member of the Tennessee State Medical Association and the Shelby County Medical Society, died in St. Joseph's Hospital, Memphis, following an operation for ulcer of the stomach, after a long illness, on January 13, aged 58 years.

Dr. Scott Fulton of Columbus, O., a graduate of the Columbus Medical College in 1892, died at his home from pneumonia after a brief illness, aged 50 years.

Dr. Harry S. Pratt of Lancaster, N. H., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1899, died at his home following an operation for appendicitis on January 6, aged 40 years.

Dr. James Albert Rowan of Wesson, Miss., a graduate of the Medical Department of the Tulane University, New Orleans, in 1873, and a member of the Mississippi State Medical Association and the Tri-County-Pike-Lincoln-Copiah Medical Society, died at his home after a long illness, on January 9, aged 62 years.

Dr. George Allen Nash of Maryville, Mo., a graduate of the St. Joseph Hospital Medical College in 1879, and a member of the American Medical Association, the Missouri State Medical Association, and the Nodaway County Medical Society, died in St. Francis Hospital, Maryville, on January 8, aged 62 years.

Dr. Henry Walton Wood of Fairhaven, Mass., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1902, and a member of the American Medical Association, and the Massachusetts and Bristol District Medical Societies, died at the Jefferson Hospital, Philadelphia, after a long illness on January 12, aged 40 years.

Dr. Edward Maxwell Wiley of Lexington, Ky., a graduate of the Medical College of Indiana, Indianapolis, in 1876, formerly superintendent of the Eastern Kentucky Asylum for the Insane, Lexing-

ton, and a member of the American Medical Association, the Kentucky State Medical Association, and the Fayette County Medical Society, died at St. Joseph's Hospital, Lexington, following an operation, on January 11, aged 64 years.

Dr. THOMAS W. TAYLOR of Henderson, Ky., a graduate of the University of Louisville Medical Department in 1845, died at his home from pneumonia after a short illness, aged 91 years.

Dr. GEORGE D. ROWE of Boone, Ia., a graduate of the Medical School of Maine, Portland, in 1868, and a member of the Iowa State and Boone County Medical Societies, died at Hot Springs, Ark., on January 13, aged 69 years.

Dr. CHARLES BOWMAN of New Albany, Ind., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1849, died at his home after a long illness on January 12, aged 89 years.

Dr. WALTER B. HILL of San Jose, Cal., a graduate of the Jefferson Medical College, Philadelphia in 1864, died at his home on January 9, aged 75 years.

Dr. DAVIS BRUCE RICHARDS died at Philadelphia on January 22 of nephritis at the age of 47 years. He was graduated from Jefferson Medical College in the class of 1894. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. WILLIAM W. KNOWLTON died at Camden, N. J., on January 23, at the age of 44 years, as a result of arteriorenal disease. He was graduated from Hahnemann and Medical College Hospital in the class of 1893. He was a member of the Camden Board of Health.

Dr. JAMES BOONE LINCOLN died of cerebral hemorrhage at Lancaster, Pa., on January 18 at the age of 57 years. He was graduated from Jefferson Medical College in the class of 1883 and he was for twenty-three years connected with medical relief department of the Pennsylvania Railroad.

Dr. ADAM M. KALBACH died at Lancaster, Pa., on January 19 at the age of 69 years. He was graduated from the Long Island College Hospital in the class of 1867 and from the Bellevue Hospital Medical College in the class of 1868.

Dr. JAMES REA CRAWFORD died suddenly of heart disease in the Polyclinic Hospital on January 15 at the age of 41 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1899.

Dr. JAMES HENRY PARKER, former president of the Cotton Exchange, New York, died at the Roosevelt Hospital on January 27, after several weeks illness from blood poisoning following an operation made necessary by an accident to his knee. Dr. Parker, who was 72 years old, was graduated in medicine soon after the close of the Civil War, during which he had served in the Confederate Army, and for a time practised in North Carolina, finally, however, entering business life. He had long been prominent in Southern circles in New York.

Dr. DUDLEY RAGLAND BOSTON of Crofton, Va., a graduate of the University of Virginia, Department of Medicine, Charlottesville, in 1854, died at his home from pneumonia, after a short illness, on January 15, aged 82 years.

Dr. GEORGE W. BROWN of Rockford, Ill., a graduate of the Eclectic Medical College of Pennsylvania, Philadelphia in 1868, died at his home on February 5, aged 95 years.

Correspondence.

DR. LYDSTON MISQUOTED.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In connection with a sensational report of an operation under the so-called "twilight sleep," there has appeared in various newspapers a statement purporting to be by myself which would imply not only that I was present at the operation but that I unequivocally endorsed the method. The following appeared in the New York *World*, January 28, 1915: "'After this demonstration,' Dr. G. Frank Lydston said, 'twilight sleep for men will become common. The use of this anesthetic will no longer be limited to childbirth cases, but women as well as men will benefit by it generally. This operation was important, and I am glad to express my professional opinion that it was completely successful.'"

I desire to state: (1) That I was not present at the aforesaid operation; (2) I never have been interviewed upon the subject nor, up to the present moment, have I expressed for publication any opinion of the so-called "twilight sleep"; (3) my present attitude toward the revival and sensational nomenclature of the employment of scopolamine-morphine hardly would comport with the sentiments expressed in the statement falsely attributed to me.

G. FRANK LYDSTON, M.D.

CHICAGO, February 4, 1915.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CHADWICK LECTURE—WAR AND DISEASE—NAVAL AND MILITARY HYGIENE—MOTOR AMBULANCES—MOTOR OPERATING THEATER—PRIZES OFFERED.

LONDON, January 22, 1915.

SIR WILLIAM COLLINS, presiding at the opening of a course of Chadwick Lectures on "War and Disease" by Professor F. M. Sandwith, remarked that for five months we had been living under the shadow of a world-wide war, so the Chadwick trustees had endeavored to adopt their program at this time. Under the powers of the trust they had now offered for the first time prizes of fifty guineas and the Chadwick gold medal for medical officers of the army and navy who most distinguished themselves in promoting the health of the soldiers and sailors. This proceeding was cordially approved by the chiefs of the medical departments and he hoped the names of the prize winners might be announced at one of the lectures of the course. In the present war, he added, we had been able to welcome the beneficial work at the front of the motor ambulances which have greatly shortened the time between the reception of a wound and its surgical treatment.

Professor Sandwith began his course by remarking that the morale of the men and the success of an army must largely depend on physical causes, such as the forethought given during peace to the feeding, hygiene, and equipment of the troops. In early campaigns hygiene received no consideration. As late as the Crimean War the backward state of both military and civil hygiene was most disastrous. Florence Nightingale, Sidney Herbert, Edwin Chadwick, Dr. Parkes worked zealously to introduce sanitary science into the life of the soldier, his barracks and his hospitals. They showed that the death rate in the British Army in India and even in the English barracks was far too high. By the

efforts of determined reformers the medical service of the army was put on a new foundation. The Royal Army Medical Corps had brought about a state of health of the British soldier to which his present endurance of trying physical conditions was to no slight extent due. Famous marches were quoted; the disastrous effects of unsuitable uniforms or of medical errors were cited. The modern uniform, the boots, the food, the drink of the soldier were compared with those of his predecessors fifty and one hundred years ago, and it was seen how attention to details had enabled him to bear with courage and cheerfulness exposure, lack of sleep, and the strain of incessant watchfulness.

The next point dwelt upon by the lecturer was the great extent to which the loss of life in war has been reduced by the precautions insisted on in recent times against the outbreak and prevalence of preventable diseases—precautions laid down and urged by the Army Medical Department.

The lecture was illustrated by lantern slides showing the uniforms of the army in bygone periods, copies of old wood cuts of military surgery, and portraits of some of the pioneers of military hygiene.

An automobile ambulance to serve as a surgical unit when operations can be performed near the front as well as in the base hospitals or in homes has been at work in the field, and some account of it has been given to the French surgical society by Dr. Hallopeau. This motor hospital, as we may call it, he described as consisting of three wagons and a traction chassis. The chassis supplies an unlimited quantity of steam and heats the operating theater, keeping the temperature constant at 75° Fahrenheit, even when outside it is only 10° Fahrenheit. The wagons carry materials for 120 beds, tanks for hospital, surgery, and kitchen. The whole hospital can be put together in a few hours. Connected with the ambulance there are six motor cars, each carrying four beds; they keep the hospital and neighboring first-aid stations in communication. On one occasion the surgeons were operating continuously for ten hours on cases thus brought quickly from the front. Only severe cases are forwarded—one day there were six of perforated intestine operated on, three of which recovered.
